THE SCIENCE OF FLOUR MILLING.

Le Froment et sa Mouture. Par Girard et Lindet. Pp. vii+355. (Paris: Gauthier-Villars, 1903.) Price 12 francs.

AT the time of the regretted death of Prof. Girard in 1898, much valuable scientific work had been accomplished by him, and the results given to the world at large. But as must almost of necessity occur when a busy man is taken away from his labours, there also remained some tasks commenced but not completed. Among these was a projected treatise on flour milling, of which, however, Prof. Girard left but the general plan and the unfinished manuscript of three chapters. These materials were entrusted to M. Lindet, who has completed the work and supplied the book now before us. The author refers to the fact that neither himself nor Prof. Girard was a practical miller, but that the book is the production of two men of science. An examination of its pages shows it to possess those merits which might be expected from the previous training of the writers, and also, it must be added, the defects which spring from the same cause.

The first chapter deals with the production of wheat in various French districts, and also with the corn markets of Paris and the provinces. In passing, it may be noted that in France, as well as in England, they still suffer from the adoption of different systems of weights and measures in the different local corn markets. Thus, Troyes has a unit of 121 kilos., while La Charente adopts 80 kilos. as its measure, and other markets intermediate quantities. The authors deplore the grave inconveniences which result from such differences, and look forward to a time when the metric quintal shall have been universally adopted. With France as the birthplace of the metric system, there is perhaps some consolation in knowing that England is not the only country ruled in this matter by old-fashioned conservatism.

Following on this introduction, the writers next deal with the chemical composition and the alimentary value of the different parts of the wheat grain. The botanical distinctions between such parts and their separation and estimation are first described, tables being given which show the relative percentages of envelopes, germ, and flour-producing kernel or endosperm in leading types of wheat. The histology, chemical composition, and analysis of the envelope are next given, particular attention being devoted to the constitution of cerealin and the important *rôle* it plays in the process of panification. In pursuit of this line of investigation, the influence of the various parts of the envelope on those milling products which ultimately find their way into the flour is examined very minutely. The experiments and arguments of Mège-Mouriès are followed closely, and his conclusions to the effect that the inclusion of branny particles in flour results in the production of dark-coloured and inferior bread are fully endorsed. The authors further conclude that the branny matters of wheat are devoid of utility for purposes of human alimentation, being practically undigested by man, and consequently inassimilable. An experiment made by Prof. Girard on himself is described at full length. Being in perfect health, and with the digestive faculties in excellent condition, he ate a quantity of pure wheat grain envelopes, and analysed these when excreted at the close of the process of digestion. The necessary precautions were of course taken to ensure exact and trustworthy data being obtained, and Prof. Girard's results show that there is practically no assimilation of proteid bodies from the bran ingested. There is, however, a certain absorption of mineral substances, but this only amounts to 4 grams of mineral matter per kilogram of bread made from "entire flour" (wholemeal). Having regard to the quantity and variety of such matter in a modern diet, the authors regard the gain of these 4 grams as having no serious importance, and, in a word, condemn entirely and without reserve the inclusion of the bran in wheaten flour.

In studying the action of the germ, the authors are impressed with the fact that fresh germ has a characteristic odour and flavour which are in themselves pleasant. They further recognise that germ contains

a large percentage of proteid and oily matter, in consequence of which the nutritive value is high. But the proteid matter contains an active ferment, and the oil is of a highly oxidisable nature, readily becoming rancid. For these reasons they do not hesitate to assert that the germ, as well as the bran, should be rejected in the act of making flour, the farinaceous endosperm being the only component of the wheat grain which ought to be used as human food. It is interesting to note that the problem of the utilisation of germ has been much more successfully attacked in England than on the Continent. The credit is due to an English miller of discovering the fact that on subjecting germ to the action of slightly superheated steam the diastasic properties of the proteids are destroyed, while the oil is so fixed as to lose its natural tendency to rancidity. Germ treated in this manner and then mixed with ordinary white flour produces a bread of pleasant flavour and of high nutritive value.

The endosperm or kernel of wheat consists principally of proteid matters, starch, and products of starch hydrolysis. Of these substances the proteid matter has received the closest attention, the whole general character of each particular variety of wheat, and of its resultant flour, being governed by the quantity and quality of the proteid bodies contained. It has been recognised from the time of Liebig to the present that the proteid matter of wheat is not a single compound, but a mixture of several distinct substances. Among these are small quantities of bodies soluble in water or dilute saline solutions respectively (albumins and globulins); but the greater portion is not soluble in either of these reagents, but forms with water a tough india-rubber-like body, to which the name of gluten has been given. This substance is readily prepared by carefully kneading and washing in a stream of water a piece of dough from wheaten flour. The starch and soluble matters are thus eliminated, and the gluten remains behind. The body thus obtained, known as wet gluten, contains about two-thirds of its weight of water, the remainder being approximately pure proteid. By appropriate means, gluten is capable of being separated into two, and possibly three, different substances, possessing distinct and characteristic chemical and physical properties.

The most exhaustive examination of these bodies has been made by Osborne and Voorhees, who in 1893 communicated their results to the *American Chemical Journal*. Following much the same lines of research as other investigators, they treated gluten and flour itself respectively with dilute alcohol (0.90 specific gravity). This reagent dissolves a considerable quantity of proteid matter from both the previously washed gluten and the untreated flour, the proteid being the same in both instances. (Albumin and globulin are insoluble in dilute alcohol.) To this proteid the name of gliadin has been given. Of gluten, the insoluble portion has been called glutenin. Osborne and Voorhees describe gliadin as being, when obtained in the dry state, from a solution in weak alcohol or water, an amorphous transparent substance closely resembling pure gelatin in appearance. It is slightly soluble in distilled water, but is instantly precipitated by a trace of common salt. Gliadin is very soluble in dilute alcohol (70 to 75 per cent.). As may be assumed from its mode of preparation, glutenin is insoluble in such alcohol, and also in water and dilute saline solutions. When freshly precipitated and hydrated, glutenin is soluble in 0.1 per cent. potash solution, and also in the slightest excess of sodium or potassium carbonate solution. Osborne and Voorhees made analyses of spring and winter American wheat flours respectively, each of which is a perfect flour of its kind, and found them to yield gliadin and glutenin in the following proportions:—

	Spring flour.	Winter flour.
Gliadin	45·8	48·4
Glutenin	54·2	51·6
	100·0	100·0

These quantities are roughly, it will be noticed, half and half, whereas M. Fleurent, whose results are adopted by MM. Girard and Lindet, states that the ideal composition of gluten is 75 parts of gliadin to 25 parts of glutenin. With such a composition the resultant bread will be well-risen and easy of digestion; but if the proportion of gliadin is higher, the bread will rise well during fermentation, but will fall in the oven, thus producing a heavy loaf as the result of the liquefaction of gliadin in the presence of water, under the influence of heat. But if the glutenin be in excess, the dough will be comparatively inelastic, and will not rise in baking.

There is evidently a great discrepancy between the results obtained by Osborne and Voorhees and those given in the work before us. It is to be regretted that MM. Girard and Lindet do not point out more clearly that in determining the percentage of gliadin M. Fleurent has made a radical departure from the method of Osborne and Voorhees. Instead of using pure dilute alcohol as a solvent, M. Fleurent employs 70 per cent. alcohol containing 3 parts of caustic potash per 1000. If, as stated by Osborne and Voorhees, glutenin is soluble in 0.1 per cent. potash solution, it is evident that it is readily soluble in a solution of the strength employed by M. Fleurent. After thus dissolving in dilute alcoholic potash solution, M. Fleurent passes carbon dioxide gas to saturation; but although potassium carbonate is insoluble in absolute alcohol, it is soluble in alcohol of 70 per cent., and so one has at the close of the experiment, not a solution of gliadin in dilute alcohol, but a solution of gliadin and a portion of the glutenin in a dilute alcohol-and-water solution of potassium carbonate. It is in consequence of this difference in their respective methods that the proportions of gliadin and glutenin found by these investigators differ so markedly from each other. No reflection whatever is cast upon the method of M. Fleurent as a means of judging the quality of a sample of flour, but it is unfortunate that the separation thus obtained is throughout spoken of by MM. Girard and Lindet as being one of gluten into gliadin and glutenin.

The examination of the more purely chemical part of this book has occupied space to the exclusion of the other subject-matter of the book. In later chapters

are contained an interesting historical *résumé* of the development of milling processes, which in turn is followed by a detailed description of wheat-storing buildings, silos, elevators and the like. The whole process of wheat cleaning, both by dry and wet methods, is described. In the next place, there is an account of the reduction of grain to flour, both by the old mill-stone process and the more modern one of gradual reduction by means of roller mills. The plan-sifter and other methods of separating flour from bran and germ next occupy attention. Having thus traced the whole operation from the raw grain to the finished flour, the authors devote a concluding chapter to flour analysis, modes of preservation, and a description of the channels through which, as a matter of commerce, it reaches the consumer. Of particular interest in this connection is the description of the "Twelve Marks" Market of Paris, and its mode of classifying and valuing flour according to a carefully selected standard of quality.

That M. Girard did not live to see the completion of his work is a matter sincerely to be regretted, but M. Lindet is to be congratulated on having produced, from the materials placed at his disposal and his own researches, a work of the keenest interest to chemists, and one that should prove of great value to the milling industry.

WILLIAM JAGO.

PHYSIOLOGICAL RESULTS.

Ergebnisse der Physiologie. Erster Jahrgang. II. Abteilung. Biophysik und Psychophysik. Pp. xviii+926. (Wiesbaden: Bergmann.) Price 25 marks.

IN the present day, when the man of science is becoming more and more overwhelmed by the ever-increasing flood of literature, any methods which can assist him in some degree to surmount the flood may cordially be welcomed. Year-books and Centralblätter are useful in affording abstracts of current literature, but such abstracts, necessarily disconnected, are apt to engender disconnection and incompleteness of thought in their readers. Moreover, mixed fragments of literature are exceedingly difficult to assimilate, in comparison with connected and critical surveys extending over a definite range of some stated subject. We must therefore express our warm approval at the publication of the first volumes of this new physiological annual. As the name might imply, this "Ergebnisse der Physiologie" is comparable in character to the well-known "Ergebnisse der Anatomie und Entwickelungsgeschichte," which has proved of great service to zoologists, and to the no less valuable "Ergebnisse der allgemeinen Pathologie." In the words of the editors (L. Asher and K. Spiro), the present "Ergebnisse" will consist of original and critical essays upon various subjects or special points in physiology, which as the result of fresh research have acquired an especial interest. As the "Ergebnisse" will appear annually, they hope that in course of time as far as possible every branch of the science will receive its due attention.

With this commendation, we may perhaps be permitted to offer some little criticism as to the range of subjects which the editors propose to include within their jurisdiction. Dealing only with what they term "Biophysik" and "Psychophysik," with which the volume under review is alone concerned (and which represent only half the complete annual), it appears that in addition to purely physiological matters, the editors intend to include essays covering a wide range of general physiology. The physiology of protoplasm is, of course, quite rightly included, but it is distinctly open to question whether biological problems such as inheritance and adaptation had not better be omitted. The present volume of "Ergebnisse," for instance, includes a very long article on Regeneration, although this subject is dealt with regularly every year in the aforementioned "Ergebnisse der Anatomie." Again, the editors intend to include articles on physiological psychology (*e.g.* simple psychical processes, reaction time, sleep, hypnotism). All these extraneous subjects go to swell the size of the volumes, and render them unwieldy. Thus this first year's issue runs to two volumes of about 900 pages each, or double the bulk of the anatomical "Ergebnisse," which in its earlier numbers much more reasonably confined itself to a single volume of about 700 pages. There must be many a working physiologist who would gladly subscribe to a volume of this character, but who would be deterred by the bulkiness and expense of the present issue. Moreover, it is difficult to see how the multiplication of articles in the present "Ergebnisse" can be kept up in the future, unless special points be dealt with in wholly unnecessary detail. So great is the total amount of ground covered that it almost seems as if one or two more years' issues would include the whole range of physiology. Subsequent essayists would accordingly have to rely almost entirely on new work, or their articles would practically resolve themselves into year-book abstracts. It is to be hoped, therefore, that the editors may see fit in future years to curtail the size of their volumes. This should be done, not only by diminishing the number of articles, but by diminishing their length. Many of the essays in the present volume, as, for instance, those of Prof. Tigerstedt on intracardial pressure, of Prof. Starling on the movements and innervation of the alimentary canal, and of Prof. Hensen on the physiology of hearing, are of a moderate and most convenient length; but others, such as those of C. v. Monakow on cortical localisation (132 pages), of A. Tschermak on adaptation of the eye to light, and the function of the rods and cones (106 pages), and of F. B. Hofmann on vision as affected by strabismus (46 pages), must be regarded as unnecessarily detailed, admirable as they may be in themselves. On the other hand, one or two articles err on the side of brevity, especially that of H. Boruttau on the innervation of respiration (6 pages), and to a less extent that of H. Meyer on nerve and muscle poisons (15 pages).

Another matter deserving of criticism is one which in future issues will doubtless to some extent be rectified. It concerns the lack of uniformity in the treatment of their subjects observed by the various essayists.

This is especially noticeable as regards the bibliography. Many of the essayists hit a happy mean, but H. Przibram actually gives 31 pages of references in his 77-page article on regeneration, whilst v. Monakow gives 846 distinct references, occupying 27 pages. Prof. Biedermann sins in the opposite direction, and in his otherwise comprehensive and instructive article on electrophysiology, sometimes mentions authors without giving any clue to their papers. Again, several of the articles are well illustrated (especially v. Monakow's important article on cortical localisation, which has eight plates), and it would be well if this most useful feature could be extended to certain other of the articles, though doubtless the question of expense comes in here.

In the limits of a short notice like the present one, it is impossible even to mention the titles of all the essays, but reference may be permitted to a few, over and above those already cited. P. Jensen gives a useful description of protoplasmic movement, and the effects of external conditions upon it, whilst J. von Uexküll writes a philosophical essay on the psychology of the lower animals. O. Langendorff enters very thoroughly into the properties of cardiac muscle, and discusses the nature of heart contraction, whether nervous or myogenic. L. Asher treats of certain aspects of the vaso-motor system, and R. du Bois-Reymond deals fully with the mechanics of respiration. H. E. Hering writes at some length on the central nervous paralysis of skeletal muscles (*e.g.* reflex inhibition, antagonistic muscles, decerebrate rigidity), whilst P. Grützner treats of the voice and speech, and H. Zwaardemaker of smell.

Finally, a word of praise must be accorded to the admirable manner in which the volume is printed. The large and well interspaced type renders reading a pleasure. Also printer's errors are remarkably infrequent.

H. M. VERNON.

PHYSICAL CHEMISTRY AND BIOLOGY.

Physikalische Chemie der Zelle und der Gewebe. Von Dr. Rudolf Höber, Privatdocent der Physiologie an der Universität Zürich. Pp. xii + 344. (Leipzig: W. Engelmann.) Price 9*s.* net.

THE keynote to this interesting volume is found in the beautiful quotation from von Humboldt with which the author introduces his preface.

"Es ist die Sitte derer, die gerne andere auf den Gipfel der Berge führen möchten, dass sie den Mitreisenden den Weg gebahnter und anmutiger schildern, als man ihn finden wird, und dass sie die Aussicht von den Bergen rühmen, auch wenn sie ahnen, dass ganze Teile der Gegend in Nebel verhüllt bleiben werden. Sie wissen, dass auch in dieser Verhüllung ein geheimnissvoller Zauber liegt, dass eine duftige Ferne den Eindruck des Sinnlich-Unendlichen hervorruft, ein Bild, dass im Geist und in den Gefühlen sich ernst und ahnungsvoll spiegelt."

The author proves himself in the subsequent pages of the volume just such an inspiring guide as this, and points out the varied prospects from many points of view in his different chapters.

The book is interestingly written throughout, and although space makes it impossible to mention all recent work in the applications of the new advancements of physical chemistry to biology, the work is thoroughly up to date in most important directions of this extensive field of research.

The author states in his preface that the book is intended as a first review of the subject for those who may subsequently study in larger text-books, and be stimulated thereby to aid in its development; but, in the opinion of the reviewer, the book will be found most interesting to those who already possess a considerable acquaintance with physical chemistry, and desire a comprehensive and suggestive review of its relationship to biology and physiology.

Parts of the subject, such, for example, as the development of the ionic theory, and equilibrium in solution, are from the size of the book presented in such concise form as to make anything but easy reading for a beginner at the subject; while others, such as the permeability of the cell membrane, the physical theory of the action of anæsthetics, absorption, secretion and lymph formation, form attractive reading, and demand little special previous knowledge of the subject.

The physical chemist owes to the biologist the earliest experimental work upon osmotic pressure and its relationship to molecular weight. It was the study of osmosis and osmotic pressure by Pfeffer and Traube on account of its relationship to cell life which chiefly led to the conception that substances in solution behave in certain respects like gases, and this formed the starting point for the physical chemistry of solutions.

For this early service biologists are now being repaid by the great opportunities which increased knowledge of physical chemistry is giving in the prosecution of the study of the chemical and physical processes taking place in the cell.

In this development of biology based on physical chemistry, the work is not being done solely by physical chemists, on the one hand, or by biologists on the other, but important contributions have been and are being made to the common store by both biologists and physical chemists. A perusal of the book before us demonstrates most clearly this mutual relationship between physical chemistry and biology, for in the names of authors one finds those both of important biologists and physical chemists.

It is along this line of physical chemistry, so far as one can foresee, that the most important and rapid growth in biology will take place in the near future, and hence it is most important for either following or taking a share in these developments that every biologist should also be acquainted with recent progress in physical chemistry. Certain portions of the book may specially be recommended to those who desire in a short space to learn something of the close practical relationship of physical chemistry to biology and also to medicine, such as that on the solubility of uric acid, urates, and the purin bodies, and on the action of indicators, pp. 88 to 101; the permeability of the cell-membrane, especially that portion dealing with the action of anæsthetics, pp. 101 to 134; action of ions upon cells, pp. 134 to 146, and 171 to 184; methods of

physico-chemical analysis, pp. 206 to 251; and lastly, the most interesting account given on pp. 272 to 315 of the physical chemistry of ferment action, and of Bredig's recent discovery of inorganic ferments.

The whole volume well deserves careful reading, and it is to be hoped that it will find a wide circle of readers amongst workers in all divisions of the very comprehensive subject of biology.

BENJAMIN MOORE.

OUR BOOK SHELF.

Contribution à l'Étude du Mode de Production de l'Electricité dans les Êtres vivants. Par M. le Dr. Louis Querton. Pp. 180. (Bruxelles: Lamartin, 1902.)

THIS contribution to the existing literature upon the subject of vital electromotive phenomena contains some new researches which support the view advocated by the author that the electrical changes in living tissues are caused by definite chemical processes. The view is not a new one, and its advocacy in the present publication appears to have been called forth by the attitude taken by Mendelsohn in his article upon the subject in the "Dictionnaire de Physiologie," edited by Prof. Richet; this attitude is described by Dr. Querton in the following quotation from M. Mendelsohn's article:—

"The conception of the chemical origin of the electrical phenomena observed in nerve and muscle is purely hypothetical."

Dr. Querton has done useful service in bringing together additional evidence that the electrical phenomena are in many cases the indications of definite chemical processes. The author gives a brief review of the general features of the phenomena in electrical organs, muscles, nerves, the eye, glandular tissue, the skin and the leaves of plants; he then describes observations of his own as to the direct connection between such electrical phenomena in plant leaves as are produced by the action of light and (photo-)chemical changes in the chlorophyll; he follows these by a description of photo-electric phenomena occurring in solutions of oxalic acid, &c.

As regards the general review, this is admittedly scanty, particularly in the part which deals with the electric organs of fishes, and in dealing with this portion of the subject the author does not appear to have recognised that recent observations point to the conclusion that the electrical organs of fishes are to be classed among nervous, and not among muscular, structures. The author's own researches show that electromotive effects may be rapidly developed, and may rapidly subside in correspondence with the similar development and subsidence of chemical changes of comparatively small amount, and this result appears to support the view of chemical causation which he advocates. It must, however, be admitted that in nervous tissues, chemical change is so slight or so masked as to give no indications of its occurrence unless, indeed, the electrical alterations are assumed to be such indications, an assumption which, for the purpose of the argument, is logically unsound. Even in the case of the pronounced electromotive effects observed in the electrical organs of fishes there is the same lack of evidence, and it would therefore seem that provided the chemical change is of a certain type, a relatively insignificant chemical alteration may be associated with very definite electromotive effect; in this connection the possibility of the occurrence of surface tension changes as the result of chemical alteration might have been treated by the author with great advantage.

The impression left on reading the author's conclusions is that, although these indicate that one antecedent of the electromotive phenomena observed in living tissues is chemical change, the more interesting question as to whether this chemical antecedent is a remote or an immediate factor in their causation remains untouched.

Statics by Algebraic and Graphic Methods. By Lewis J. Johnson, C.E. Pp. viii+134; with six plates. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 2 dollars.

FROM the preface we infer that the author has set out with the object of providing engineering students with a text-book of small compass in which the elementary parts of statics are treated on a deductive basis, and analytical and graphical methods of solution are treated side by side.

It cannot be said that the book fulfils either of these objects as adequately as it should. The proofs of the conditions of equilibrium and of the parallelogram of forces are so unsound that it would be far better to replace them by a few definite axiomatic statements. As an example, take the statement in the footnote on p. 14 (in connection with the moment of a force about a point), "For assuming the point to be fixed is really assuming it to be always subject to a force equal, opposite and parallel to the given one."

In regard to the graphic solution of problems, it is possible that when a student has been told how to draw a force diagram, he may apply the method to an example, and actually measure the lines representing the forces, the only drawback being that in the questions the angles of the figures are not specified, and the figures are too small to give good scale diagrams without this help. The so-called algebraic solutions are too suggestive of the well-known type of examination answer, "By taking moments the resultant can be found." This usually means that the candidate cannot find it. The best feature of the book is the set of six typical problems which are actually solved by both methods on the plates at the end.

De l'Expérience en Géometrie. Par C. de Freycinet. Pp. 178. (Paris: Gauthier Villars, 1903.) Price 4 francs.

THE author discusses the question whether geometry is purely a rational science or whether it also possesses an experimental side. The question is dealt with in connection with (1) the concepts of geometry, (2) geometrical axioms, and (3) the propositions the establishment of which forms the object of deductive geometry. In the first chapter, M. de Freycinet finds no *a priori* reasons for the existence of such concepts as space, straight line, curved line, plane or curved surface, volume, angle, parallelism, tangency. These and other concepts are all suggested to us by our perception of the material universe. Passing on to the axioms relating to the straight line and plane, the author considers that it can in no sense be regarded as a self-evident truth that the straight line is the shortest line between two points, that a straight line can be produced indefinitely in either direction, or that two straight lines cannot have two points in common. These and other similar facts can only be regarded as results of experience and observation. In comparing the purely geometrical methods of the ancients with the analytical methods of Descartes and Leibnitz, the latter methods will be found in reality to be no less concrete in their foundations than the former. They do not discuss the geometrical truths of which they make use, but they accept them as evident, relying on pure geometry to establish them.

The general conclusion is that geometry is largely based on the results of experience. M. de Freycinet's book should prove of great interest to all who devote attention to the teaching of geometry.

Étude des Phénomènes volcaniques: Tremblements de Terre—Eruptions volcaniques—Le Cataclysme de la Martinique, 1902. Par François Miron. Pp. viii + 320. (Paris: Ch. Béranger, 1903.)

THE ground which this little work is intended to cover is so vast that it is impossible for the author to deal with any part of the subject in an adequate manner. Seismology is dismissed in twenty-seven pages, which serve only to give a most misleading impression of the present state of our knowledge of that science. The ninety-nine pages devoted to volcanic eruptions furnish only a short sketch of the subject, such as may be found in any treatise on geology, though here and there matters not ordinarily treated of in text-books may be met with, such as Fouqué's method of collecting gas at fumaroles. The thirty-eight pages devoted to the causes of vulcanism contain summary statements of the views of de Lapparent, Fouqué, Stanislas Meunier, Gautier and others, the author giving greatest weight to astronomical causes as possibly determining volcanic outbursts! To the phenomena following volcanic eruptions sixteen pages are devoted, while an account of the principal volcanoes of the globe occupies forty-two pages. The description of the Martinique and St. Vincent eruptions has, however, seventy pages devoted to it, and the work concludes with chapters in which vulcanism and the riches of the globe are discussed, such matters as mineral veins, thermal springs, and the occurrence of petroleum being hastily passed in review.

It is difficult to understand what useful purpose a compilation of this kind can serve, but, as the author says in his preface, general attention has been attracted by the catastrophe of St. Pierre, and there seems to be a demand for some kind of popular information on the subject. The supply possibly meets the demand, but both are probably ephemeral.

Experiments with Vacuum Tubes. By Sir D. L. Salomons, Bart. Pp. vii+49. (London: Whittaker and Co., 1903.) Price 2s.

GIVEN a well-equipped physical laboratory and an expert glass blower as assistant, one could pass many a pleasant hour in repeating the experiments described in this little book. The phenomena exhibited by vacuum tubes are perhaps the most fascinating that electrical science can show; they possess a rare and peculiar beauty which, like that of the rainbow or the Aurora, appeals to both the æsthetic and the scientific senses. Sir David Salomons describes how tubes may be constructed to produce certain definite results in the arrangement of striæ and so forth, and many of the designs give evidence of painstaking ingenuity. A number of experiments with tubes and magnets are also described, some of which serve to illustrate well the mutual action of electric currents and magnetic fields. The author does not deal with those phenomena which, in the hands of Sir W. Crookes, J. J. Thomson and others, have led in recent years to results of such importance; indeed, the theoretical explanations which are given as a running commentary on the experiments seem rather to show a lack of appreciation of the essential facts which have added such interest to the behaviour of the electric discharge in high vacua, and have raised the vacuum tube from the position of a scientific toy to that of a powerful instrument of research.

M. S.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Energy Emitted by Radio-active Bodies.

PROF. J. J. THOMSON'S interesting article in last week's NATURE raises the question of how long the emission of energy by radium may be expected to continue. I think in this connection that it would be of great importance to determine, if possible, whether radium, as contained in pitchblende, emits as much energy as the same amount of the material in the form of an artificially concentrated product. The mineral must be supposed to have been in existence, in its present condition, for a period of time comparable with the age of the earth—perhaps 50 million years. It is certainly more likely to have lost than gained activity during that time. We may therefore reasonably assume that it has been liberating energy at not less than its present rate for 50 million years. A determination of the amount of energy thus emitted would carry us much further than the most careful and protracted observations on powerful radium preparations.

Such a measurement would, no doubt, be difficult, but not, I think, altogether impracticable. A very large block of pitchblende might be used, and a thermocouple inserted in the centre of it. Something might be gained by careful heat insulation of the block.

A rough calculation will show the rise of temperature to be expected.

Consider an infinite slab of pitchblende bounded by two plane faces, the axis of x being perpendicular to these faces. Take an elementary slice, of thickness δx, at distance x from the face, and bounded by planes parallel to it.

The outflow of heat per square cm. from this slice is $-k\frac{d^2\theta}{dx^2}\delta x$, where k is the thermal conductivity, and θ the temperature.

When a steady state has been reached, this must equal the rate of generation of heat in the slice per square cm. $= q\delta x$ suppose.

Thus $$-k\frac{d^2\theta}{dx^2}\delta x = q\delta x,$$

or $$\frac{d^2\theta}{dx^2} = -\frac{q}{k},$$

and by integration $\theta = \frac{-q}{2k}(x^2 + ax + b)$.

If the faces of the slab are maintained at 0° C., and if the slab is 1 metre thick, we have

$$\begin{cases}\theta = 0 \text{ when } x = 0, \\ \theta = 0 \text{ when } x = 100.\end{cases}$$

Thus $$a = -100, \ b = 0,$$

and $$\theta = \frac{-qx}{2k}(x - 100).$$

We may take for k the value 0.005, which is a rough general average for the conductivity of rocks.

It was found by Curie that 1 gram of radium emitted 100 calories per hour. If we suppose that the density of the radium is 3, and that pitchblende contains one part of it in 100,000 by volume, then, if the pitchblende is as active as one would expect from the proportion of radium contained, we should have

$$q = \frac{1}{1200000}.$$

We can now calculate the temperature to be expected at any point of the slab. In the middle, where $x=50$, we find

$$\theta = \tfrac{1}{8} \text{ nearly.}$$

So that the middle of the slab would be $\frac{1}{8}$° hotter than the faces.

In practice the difference of temperature available would be less, since the block used would not take the form of an infinite slab. But still, the effect would probably be measurable.

R. J. STRUTT.

The Fossil Man of Lansing, Kansas.

A GOOD deal of discussion has recently been aroused in America by the discovery of the so-called "fossil man of Lansing." It seems worth while considering the probable stature of the individual to whom the bones belonged. Prof. S. W. Williston, of Chicago, gives in the *Popular Science Monthly* for March (p. 470) the following values for the bone lengths, without, however, stating how the measurements were taken:—Femur, 43.0 cm.; Tibia, 35.0 cm.; Humerus, 30.2 cm.; Radius, 25.0 cm. From my memoir on the "Reconstruction of the Stature of Prehistoric Races" (*Phil. Trans.*, vol. cxcii. A, pp. 169–244), by using the formulæ on p. 196 Dr. Alice Lee has obtained the following results in cms.:—

Bones used in Reconstruction	Supposed ♂	Supposed ♀
(*a*) Femur ...	162·1	156·5
(*b*) Humerus	158·0	154·6
(*c*) Tibia ...	161·8	157·1
(*d*) Radius ...	167·7	164·8
(*e*) Femur + Tibia	161·7	157·0
(*f*) Femur, Tibia ...	161·7	157·0
(*g*) Humerus + Radius	162·4	159·8
(*h*) Humerus, Radius	159·7	155·5
(*i*) Femur, Humerus	159·6	156·0
(*k*) Femur, Tibia, Radius, Humerus	158·3	154·5

Now my experience of reconstruction shows me that with primitive races we do not get from formulæ based on modern data very consistent results when the radius is used.[1] I believe (*a*), (*f*) and (*i*) are the best formulæ to take in such cases. Effecting a perhaps not wholly defensible smoothing by taking means we have:—

Stature of Lansing individual	If ♂	If ♀
From all formulæ ..	161·3	157·3
From (*a*), (*f*) and (*i*) ..	161·2	156·5

The mean deviation of all the formulæ from the mean of the set is on the assumption that the bones belonged to a man 1·91, and on the assumption that they belonged to a woman 2·02. Thus the formulæ run from both aspects slightly more smoothly if we assume the bones to be those of a man. The skull may possibly offer, on closer study, some balance of characters on which to form an appreciation as to sex. Prof. Williston's photographs, having regard to the lower mandible and brows, do not seem wholly inconsistent with the male sex.

As to the date of the Lansing bones, this can only be settled by the geologists on the spot. But if the period be at all comparable with that of Palæolithic man in Europe, of whom, I think, we may put the best available estimate of stature to be 162·7 cm., the American and European statures, so far as such slender evidence goes, are not widely apart. If, on the other hand, we take the bones to be those of a woman, the stature of 157·3 cm. would correspond to a male stature of 169·0 cm.—a value considerably above that of Palæolithic man in Europe, or, indeed, of Neolithic man.

Hence I would suggest the following points for consideration:—

A. *The bones are those of a man.*

If they belong to those of an "early" American man,

(*a*) He was, if a normal example, of much the stature of Palæolithic man in Europe.

(*b*) He must have been a short man for his race, if early American man was much taller than the European Palæolithic man.

B. *The bones are those of a woman.*

If they belong to those of an "early" American woman,

(*a*) The early Americans, if she were a normal example of a woman, had a male stature of 169 cm., and were a taller race than early European man.

(*b*) She must have been a tall woman for her race, if early European and American men were at all similar in stature.

The stature of the American Indian is very considerable; if, therefore, a great antiquity can be predicted, *i.e.* if the silt would seem to show that the bones have been many thousand years embedded, the importance of determining the sex becomes obvious. No dogmatic statement, remembering the variability of human stature, can be made, but the find gives a *slight* probability in favour of American early man and European Palæolithic man not diverging widely in stature, if the bones are male, but, on the other hand, if the bones are female, they give a *slight* probability in favour of American early man being much taller than European Palæolithic man.

[1] Everything tends to show a shortening of the radius relative to the length of the other long bones, since early times.

It is easy to make irresponsible suggestions at a distance, but is it not possible for a systematic investigation to be made by excavating the whole, or a large part, of the deposit upon the limestone bed at Concannon's house, with the hope of discovering further human remains, or signs of human handicraft?

KARL PEARSON.

Reform in School Geometry.

THE reviews in your issue of April 23 tend to confirm an apprehension I have long felt. Euclid is to be abolished, and another sequence of propositions substituted. But it is probable that in many cases the same old methods of teaching will be retained, the same old drudgery of learning propositions and not learning to think, will be gone through by the future generation as it has been gone through by the past. The only difference will be that the one redeeming feature of the old system, the semblance of a logical sequence, will be abolished, and students will be commended instead of condemned for assuming constructions before they have learnt how to perform them. They will also be encouraged to base their proofs on such difficult-to-be-understood concepts as *direction*.

Now it appears to me that instead of the new geometry being a recent innovation, its essential features are pretty well laid down in the "Treatise on Geometry" published in 1871 by the late Dr. Watson (Longmans' Text-books of Science). The disadvantages of Euclid's order of treatment, the use of hypothetical constructions, the importance of loci, the classification of propositions, all these and many other points on which stress is now laid are discussed in Dr. Watson's preface. Whether or not would-be reformers of mathematical teaching have studied Watson, it is interesting to find the supposed "modern up-to-date improvements" in the teaching of geometry so closely forestalled in a book of thirty years ago, just as the so-called "modern free wheel" was commonly fitted to tricycles from 1879 onwards, until cyclists were glad when a substitute was invented.

G. H. BRYAN.

I WILL not deny that some reformers desire to abolish Euclid and establish another sequence of propositions in abstract geometry for schoolboys; but if Prof. Bryan reads the reviews which he cites more carefully, he will see that the reform current is very strong in quite another direction, and that his long-held apprehension is altogether baseless. I think that I apprehend the idea underlying the efforts of the majority of the reformers. It is the very old idea that the average English boy may be educated through the doing of things rather than through abstract reasoning. If abstract geometry is to be retained as a school subject, it can only in the future, as in the past, do harm to 98 per cent. of the boys; we say, drop it altogether in schools, and think of it only in connection with the universities. Two per cent. of schoolboys take to abstract reasoning as ducks take to water, and they ought not to be discouraged from the study of Euclid, but they and all the other boys ought to study geometry experimentally, logic entering into the study just as it enters into other parts of experimental physics. If the best modern books have a fault, it lies in the absurd assumption that an experimental sequence ought to have some connection with the Euclidean sequence.

JOHN PERRY.

Can Dogs Reason?

MY account of an experiment which you allowed me to record in NATURE of April 16 has been copied into a number of newspapers, and has brought me no few letters. Some of my correspondents explain the negative results of the box-meat experiment by supposing that the dog was too well trained to "steal" the meat. They have not noticed that I was careful to point out that the box was placed in the yard in which the dog is accustomed to be fed, that

he was very eager to get the meat out of it, and that when later in the day he succeeded, he showed no manner of misgiving as to his legal right to its possession.

Other of my correspondents misunderstand the purpose of the experiment. They see in it a desire to belittle their canine pets. This was very far from my thoughts. We have innumerable anecdotes telling us what dogs can do. I wish, partly I admit with a view to enabling us to sort these stories, to obtain, as data, definite observations showing what dogs will not do. Into most dog stories there creeps the little touch of human nature which makes them and ourselves akin.

Mine is the point of view of an anatomist. A dog has a brain very different from that of man. Brain and mind are the two sides of the same coin; or rather, brain is the coin, mind its value. The dog's brain cannot make a man's thoughts. How near can we come to picturing to ourselves the nature of a dog's thoughts? Without committing ourselves to Flechsig's theory of the division of the cortex of the brain into "projection areas" and "association areas," we may on anatomical grounds assert that the cortex of a dog's brain contains fewer association elements than does that of a man. It is an apparatus for transforming sensory impressions into actions, in a more limited and exclusive degree. Probably we can best picture to ourselves the work that it does by supposing that the wordless thoughts of animals are direct combinations of sensory impressions; whereas man has invented symbols for his sensory impressions. He works the symbols into thought. Nor do his symbols stand for material objects alone. They also stand for inferences from observations. But this is a subject which perhaps I ought not to touch without having at my disposal more space than I can ask you to give me in your Journal.

We must admit with Sir William Ramsay that dogs make use, in their mental operations, of sensory impressions and not of inferences, although I dissent from his qualification of their impressions of smell as "vague." It is my object to ascertain, by means, if possible, of observations which can be made under properly controlled conditions upon numerous dogs of various breeds, the limits of their power of substituting inferences for sensory impressions as materials of thought.

Perhaps I may be allowed to use a new nomenclature in defining the position in which, as it appears to me, we stand with regard to the axioms of animal psychology at the present time. An animal remembers. When it performs an action a picture of the action is stored in memory. If the result of the action be satisfactory, a picture of this result is stored in memory. When in future the animal desires to obtain the result it repeats the action. This we may call the product of "reasoning in the first degree." Action depends upon inference. We may accept it as an axiom that an animal can draw an inference of this kind. It is not yet established, by experimental methods, that an animal can combine two inferences, or, as I venture to term it, "reason in the second degree." My box-experiment was intended to throw light upon this question. I shall be very grateful for any further suggestions of possible experiments of the same kind.

ALEX. HILL.

Downing Lodge, May 2.

Spherical Aberration of the Eye.

WITH reference to the experiment described by Mr. E. Edser (p. 559) as appearing to have "escaped observation," perhaps I may be allowed to state that this phenomenon was (to the best of my recollection) described by me before the School Natural History Society when I was a boy at Rugby, about 1873–1874. I could not explain it, and no one at the meeting had any suggestion to make.

I think I connected it in my mind with irradiation phenomena, though I was baffled by the fact that the *whole* line is bent.

If the black horizontal lines drawn between different advertisements on the outside of NATURE be held five or six inches from the eye, and the rounded end of a pen be brought down close to the eye, the whole line will be seen to curve upward to meet the pen, becoming also blacker and more distinct.

W. L.

THE phenomenon mentioned by W. L. must have frequently been noticed; while resembling that described by me as a proof of the spherical aberration of the eye, it is yet due to an essentially different cause. The black line, when placed at a distance of five or six inches from the eye, is within the shortest distance of distinct vision from the latter. A point source of light, situated on the axis of the eye, at a position closer to the eye than the "near point," produces a relatively large spot of light on the retina. If the pupil be now progressively covered from above, the rays passing through the middle and upper part of the pupil will be cut off, so that those passing through the lower part of the pupil alone remain; these cut the retina in a comparatively restricted area below the point of intersection by the axis of the eye, so that the image apparently rises, at the same time becoming more sharply defined. Under the conditions mentioned, the same phenomenon would be observed if the eye were entirely free from spherical aberration. For this reason I stated that the black band should be placed "just beyond the shortest distance of distinct vision from the eye; . . . care must be taken to keep the eye carefully focused on the edge of the black band, or an exaggerated displacement, due to relaxation of the accommodation of the eye, may result." It was merely as a proof of the spherical aberration of the eye that I described this experiment as having apparently escaped observation.

April 12. EDWIN EDSER.

IN connection with the experiment on the spherical aberration of the eye, described in your issue of April 16, I may relate a striking observation I made some years ago. Regard with one eye any light or bright object on the wall, turn the head away until the object is just covered by the line of the nose; then move the eye to its natural position, and the object will reappear, supposing the nose is not too prominent. Moving the eye several times to and fro, the phenomenon will be easily observed.

Leipzig, April 29. W. BETZ.

THE SOLAR AND METEOROLOGICAL CYCLE OF THIRTY-FIVE YEARS.

THE fact that the rainfall of many regions of the earth's surface has, for the last decade or more, been gradually diminishing has led many inquiries to be made concerning the possible periodicity of this meteorological element, and during the last few months more general attention has been drawn to this interesting question. The great importance of this inquiry, not only to agriculturists but to others, renders it desirable that all facts which may tend to elucidate the subject should be thoroughly discussed.

The object of the present article is to bring together, without entering into too great detail, a few statistics relating to the rainfall of different stations in various parts of the earth to see whether there be grounds for assuming a continuation of the present small supply, or whether a greater abundance may be looked for with special reference to the condition of the British Isles.

A few introductory remarks may here not be out of place. Eduard Brückner first discovered that wet periods, great droughts, &c., occurred at intervals of about thirty-five years, and he published his important conclusions in a volume which was, and still is, a valuable contribution to meteorological science. To take one element only, namely, rainfall, Brückner showed that during the last century the mean epochs of the wet years were 1815, 1846–50, and 1876–80, while those for the dry years were 1831–35 and 1861–65.

Since the publication of this volume, many workers have studied rainfall and other records extending over long periods of time. Thus, to take one instance among many that might be cited, Herr Hofrath Julius Hann, the distinguished late director of the Vienna Meteorological Institute, made a minute investigation of the

rainfalls of Mailand, Padua, and Klagenfurt, and found a well-marked recurrence of the wet and dry periods every thirty-five years, the mean epochs of the former being 1808, 1843, and 1878, and of the latter 1823, 1859, and 1893.

In determining the variation of rainfall over such long periods as that of thirty-five years, it is necessary, if possible, to smooth the curve representing the variation from year to year, for this curve, as a rule, displays large fluctuations from the normal in the course of a very few years, and it is not easy for the eye to grasp the longer periods of variation; these long periods may to some extent be rendered more apparent by coupling up together the mean values of the rainfall for several years, and forming another mean, but somewhat fictitious value, for each successive year. Thus, for instance, the mean for one year, say 1870, might be computed from the means of the five years 1868 to 1872, or the means for 1871 from the mean of the years 1869 to 1873; instead of a five-year mean, a ten-year or a fifteen-year might be chosen.

In the figure here given, five-year means have been adopted, and the curves resulting from these have been further smoothed by drawing freehand another curve to eliminate as far as possible the smaller fluctuations of short period that still exist, even after still minor changes have been eliminated. The stations, the rainfall curves of which are here given, have not been specially selected, but simply taken as the data for them were easily available, and they afforded long records for the study of such variations as are here discussed. The short curve for the British Isles is attached so that not only can a comparison be made of this record of the Meteorological Office with that obtained by the late Mr. Symons, but that the actual variation over the islands taken together can be compared with two widely separated stations in them, as Greenwich and Rothesay. The European continent is here represented by Brussels, the epochs of the maxima and minima of the rainfall curve of which can be compared with the values given by Hann and referred to in a previous paragraph. Two stations in India, Bombay and Madras, one station in South Africa, Cape Town Observatory, and lastly three stations in the United States of America representing the rainfall of the Upper Ohio Valley, complete the rainfall information here given.

A general collective glance at these curves shows that there is an undoubted long period variation in all the stations here brought together. Further, that the periods of greatest rainfall occur *generally* in the years 1815, 1845, and 1878–83, while those at which the rainfall is decidedly deficient are about the years 1825–30, 1860, and 1893–5.

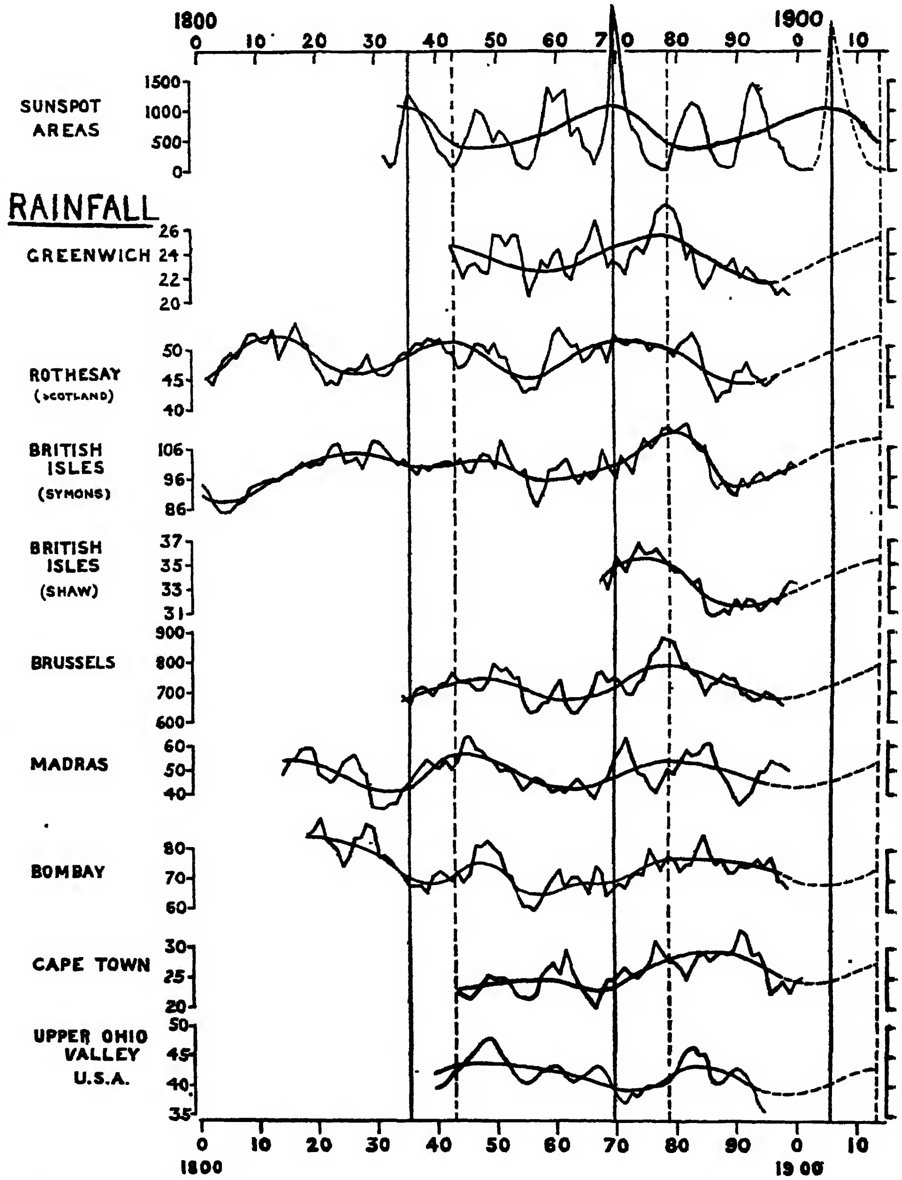

FIG. 1.—Curves showing the relation between the 35-year sunspot period and that of the Brückner rainfall cycle. Each of the rainfall curves is determined from the means of five-years, and these curves are smoothed by freehand drawing in order to show the long period variation of rainfall. The smoothed curve through the eleven-year sunspot curves indicates the epochs of the long period sunspot variation.

With the existence of these very definite fluctuations it is important to notice that the last minimum or dry period which is most apparent in the case of the curves representing the British rainfall seems now to be just

past, or on the point of coming to a conclusion, and in all cases the general tendency of the long period curve is now to rise again. This indication of the increase of the rainfall is represented in the figure by the dotted continuation of the secular variation curves for each station, and should the apparent law hold good, there seems sufficient evidence to mark that this rise will continue to take place until about the year 1913, which year will suggest the middle of the next wet epoch.

It may be mentioned, however, that owing to the great oscillatory nature of the rainfall from year to year, this rise only represents the mean rise when several years are coupled together; there may be comparatively dry years even when the secular variation curve is at a maximum, but on the average they will probably be wet.

What causes this long period of weather variation is not yet definitely known, but it is of the highest importance to meteorological science that the matter should be cleared up as soon as possible, for not only is our rainfall involved, but all other meteorological elements show similar fluctuations.

Brückner attempted to account for this long period weather cycle by attributing its origin to a change in the activity of the sun, and he investigated the sunspot data then available for evidence of a periodicity of about thirty-five years. He was not, however, successful in his research, but he concluded that, although this variation must really exist in the sun, yet it might not necessarily be indicated by sunspots. More recently a minute examination of the sunspot observations made since the year 1832, when a systematic method of observation had been initiated, has led to the discovery of such a period, a detailed account of which appeared in a previous number of this Journal (NATURE, vol. lxiv. p. 196). It was there shown that each sunspot period (reckoning from minimum to minimum) differed in many respects from the one immediately preceding or following it. Some periods, for instance, were not only more "spotted" than others, that is, the summation of the whole spotted area from one minimum to the next varied regularly, but these particular periods were closely associated with comparatively rapid rises from minimum to maximum in those periods. These changes further seemed to be undergoing a regular variation, the cycle of which was determined to be about thirty-five years.

The connection between Brückner's cycle and this long period solar change of thirty-five years was there briefly stated, and it was shown that at those two epochs of sunspot minima, namely, 1843 and 1878, which follow the cycles of greatest spotted area, the Brückner rainfall cycle was at a maximum.

The close correspondence of the epochs of these two cycles suggested at once a probable cause and effect, a cause which Brückner himself had suggested and looked for, but unfortunately did not find.

In the accompanying figure the uppermost curve represents the sunspot curve from the year 1832, and the minima just referred to are indicated by the vertical dotted lines, which are continued through all the curves. The periods of greatest spotted area just precede these epochs, and the times of maxima are shown by the vertical continuous lines drawn in a similar manner. To show the probable times of the recurrence of these epochs during a portion of the next great period of thirty-five years two vertical lines have been inserted at the years 1905, which is the probable epoch of the next great maximum, and 1913, the following minimum, so that their relation to the probable variation of rainfall, as indicated by the dotted portions of the curves, can be seen at a glance.

In conclusion, attention may be drawn to the fact that during the last few years a far more close connection between solar and meteorological phenomena has been made out than was the case some years ago, and since this long period rainfall cycle synchronises so well with the solar changes, the latter may render valuable assistance in determining the epochs of these dry and wet cycles. WILLIAM J. S. LOCKYER.

ETIOLATION.[1]

THIS monograph is published by the aid of the Daly Lydig fund bequeathed by Charles P. Daly, and embodies the results of the author's investigations extending from 1895 to 1902, and one of the first questions it arouses is, to what extent is this sustained experimental work stimulated by the certainty of adequate publication owing to the generosity of patriotic endowment, and to what extent does such work react on the pockets of friendly millionaires and induce the endowments for further work? In any case, Americans are fortunate in their circumstances in these respects.

The book, which comprises more than 300 pages of text and 176 figures, all admirably done, is divided into three principal sections. There is, first, a summary of the history of the subject, beginning with Ray (1686) and Hales (1727), and occupying 34 pages of more or less critical notes. It is, of course, impossible for us to verify the enormous number of the references to this part of the subject, but if the author has made many such blunders as those on pp. 27 and 29, where on two separate occasions he cites volumes and pages as from *Proc. Roy. Soc.* when he should have written *Philosophical Transactions*, the value of his bibliography must suffer. If a leading American plant physiologist does not know the difference between the two publications referred to, it is time he did; if he *does*, the inference that he has not consulted the original memoirs is as inevitable as it is dispiriting.

The second chief division of the work occupies the bulk of the book, pp. 35–200, and reflects credit on the author and his pupils for their industry and clearness of description, as well as for the interesting choice of plants selected for experiment. These include not only ordinary flowering plants, but also more out of the way forms of monocotyledons and dicotyledons, as well as ferns, Equisetum, &c. The one note of disappointment in this portion of the book will be struck by the want of plan. Numbers of most interesting observations on the behaviour of particular species in the dark, and illustrations of their facies, their anatomy compared with that of normal plants, their curves of growth and so forth will make the book useful to all investigators; but the plants are arranged in alphabetical order, and when the reader turns to a particular species he has no guide as to how it will be treated. Thus, taking at random Salvia, Sansevieria, Sarracenia, Saururus, and Sparaxis, which follow in the order given on pp. 171–180. The first merely heads a small paragraph stating that the corolla is atrophied in darkness. Under Sansevieria the etiolation of the shoot is described only in so far as external changes are concerned. In Sarracenia the effects of etiolation on the histology of the epidermis lining the "pitchers" are well illustrated. In Saururus figures of the anatomy of etiolated and normal stems, and measurements of height and thick-

[1] "The Influence of Light and Darkness upon Growth and Development." By D. T. Macdougal, Ph.D., Mem. New York Bot. Garden. Vol. ii. Pp. xiii + 319. (1903.)

ness form the theme; while Sparaxis heads a short paragraph recording failure of growth.

All this suggests a heterogeneous collection of student's notes as the groundwork of the memoir, and interesting and useful as many of these are, they might have been rendered more valuable by classification and efficient editing.

The third portion of the book is occupied with general considerations, and embraces summaries of the foregoing, theories as to the nature of etiolation, and so forth.

Here, of course, we look for the author's own views, but with the exception of vague statements here and there, the concluding portions of the book force us reluctantly to decide that, important and interesting as the memoir is, it is so not so much as a work of original thought and suggestion, but as an extensive and more or less critical survey of what others have done. In this category it stands well, and may be recommended, but we do not like such sentences as the following exercise for the grammarian and the physicist:—

"It is, of course, entirely probable that the action of light may set up chemical processes in the plant is in a manner entirely stimulative, and independent of any communication or transformation of energy" (p. 201).

PROF. J. WILLARD GIBBS.

THE announcement of the death of Prof. J. Willard Gibbs, of Yale University, will be received with the deepest regret by the whole of the scientific world.

There are few workers who have done so much as Prof. Willard Gibbs to teach the lesson that it is to the mathematician that the experimentalist must look for new ideas. The papers which have made his name famous date from 1873, when he published in the *Transactions* of the Connecticut Academy his paper on the geometrical representation of the thermodynamical properties of bodies. Gibbs first discussed the advantages of using different thermodynamical variables for graphic representation, and then discussed the surface formed by taking as coordinates the volume, entropy and energy of a body. "Gibbs's thermodynamical model," or "thermodynamic surface" as it is now called, has become best known to English readers through the account given in Maxwell's "Theory of Heat." The study of the properties of thermodynamical surfaces has afforded a wide field of research, which is still continuing to yield new results in the hands of the Dutch school of physicochemists. A remarkable feature of the investigation is the geometric representation of the conditions of thermodynamic stability, which does much to remove the difficulties attaching to any algebraic form of enunciation. A further paper, entitled "Graphic Methods in the Thermodynamics of Fluids," was published in 1878.

Gibbs's epoch-making papers *par excellence* are, however, those dealing with the equilibrium of heterogeneous systems, the first of which, dealing with chemical phenomena, was published in June, 1876, while the second, dealing with capillarity and electricity, appeared in July, 1878. The most essential feature of Gibbs's discoveries consists in the extension of the notion of the thermodynamical potential to mixtures consisting of a number of different components, and the establishment of the properties that this potential is a linear function of certain quantities which Gibbs has called the potentials of the components, and that where the same component is present in different phases which remain in equilibrium with each other, its potential is the same in all the phases, besides which the pressures and temperatures of the phases are equal.

The importance of these results was not realised for a considerable time. It was difficult for the experimentalist to appreciate a memoir in which the treatment is highly mathematical and theoretical, and in which but little attempt is made to reduce conclusions to the language of the chemist; moreover, it is not unnatural to find the pioneer dwelling at considerable length on comparatively infertile regions of the newly-explored territory, while points of vantage which have subsequently proved to be the most productive fields of study were dismissed very briefly. It was largely due to Prof. van der Waals that two new and important fundamental laws were discovered in the paper, namely, the phase rule and the law of critical states, and the consequences of the first of these laws were the subject of remarkable developments in the hands of Bakhuis Roozboom, Schreinmakers, Stortenbeker and Wilder Bancroft. The well-cultivated tracts of knowledge which represent a most important branch of modern physical chemistry bear but little resemblance to the crude, often circuitous path, full of stumbling blocks and difficult obstacles by which Gibbs first opened up this region. The study of dissociation phenomena has afforded some of the most beautiful experimental verifications of Gibbs's theories, which have done much to convert theoretical chemistry into a branch of applied mathematics.

It is not the physicist and chemist alone who are indebted to Prof. Gibbs; he has also made his mark among mathematicians in connection with the study of quaternions and vector algebra. Physicists claim that in the Hamiltonian system of quaternions there is a loss of naturalness from the fact that the square of a vector becomes negative. Gibbs met the objection by suggesting an algebra of vectors with a new notation, the expression for the product of two vectors being formed in such a way as to give a positive value for the square of a vector. His paper on "Multiple Algebra" was published in the *Proceedings* of the American Association for 1886.

Gibbs's attention has recently been turned to remodelling the mathematical theories underlying the kinetic theory of gases, and the law of partition of energy. His work on statistical mechanics has been before us for about a year, but so difficult is the subject that a considerable further time must elapse before it can be widely understood and appreciated. His interpretation of the determinantal equation as the principle of conservation of extension in phase, his methods of dealing with ensembles of systems, and his establishment of the existence of irreversible phenomena in connection with such ensembles are all distinct advances, but in connection with the last-named properties an idea necessarily forces itself on one that there must be some assumption underlying the proof which might with advantage be discussed more explicitly than was done in the treatise in question, and his loss at the present time deprives us of the prospect of further enlightenment on difficulties which no amount of mere mathematical formulæ will clear up.

As mentioned last week, he was elected Foreign Member of the Royal Society in 1897, and received the Copley medal in 1901. He was also an honorary or corresponding member of the British Association, the Cambridge Philosophical Society, and many other learned societies both in this country and abroad.

G. H. B.

NOTES.

THE annual conversazione of the Royal Society will be held on Friday, May 15.

THE following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the Society:—Dr. W. M. Bayliss, Prof. T. W. Bridge, Dr. S. Monckton Copeman, Mr. Horace Darwin, Mr. W. P. Hiern, Mr. H. R. A. Mallock, Prof. D. Orme Masson, Mr. Arthur G. Perkin, Prof. E. Rutherford, Prof. R. A. Sampson, Mr. J. E. Stead, Mr. A. Strahan, Prof. J. Symington, Prof. J. S. Townsend, and Mr. A. N. Whitehead.

AT the annual general meeting of the Institution of Civil Engineers, held on April 29, Sir William H. White, K.C.B., F.R.S., was elected president for the sessional year 1903–1904.

DR. P. CHALMERS MITCHELL has been elected secretary of the Zoological Society in the place of Mr. W. L. Sclater, who held the office as acting secretary since the retirement of his father, Dr. P. L. Sclater, F.R.S., last year.

FURTHER particulars of the work and position of the National Antarctic Expedition have been brought by the New Zealand mail, and are published in Wednesday's *Times*. The chief scientific work accomplished by the expedition is summarised as follows:—(1) The discovery of extensive land at the east extremity of the great ice barrier. (2) The discovery that MacMurdo Bay is not a "bay," but a strait, and that Mounts Erebus and Terror form part of a comparatively small island. (3) The discovery of good winter quarters in a high latitude—viz. 77° 50′ S., 166° 42′ E.—with land close by suitable for the erection of the magnetic observatories, &c. The lowest temperature experienced was 92° of frost Fahrenheit. (4) An immense amount of scientific work over twelve months in winter quarters, principally physical and biological. (5) Numerous and extensive sledge journeys in the spring and summer, covering a good many thousand miles, of which the principal is Captain Scott's journey, upon which a latitude of 82° 17′ south was attained, and an immense tract of new land discovered and charted as far as 83° 30′ south, with peaks and ranges of mountains as high as 14,000 feet. (6) The great continental inland ice reached westwards at a considerable distance from the coast and at an altitude of 9000 feet. (7) A considerable amount of magnetic work at sea, also soundings, deep-sea dredging, &c. Commander Scott's narrative of the expedition and statement of scientific observations, telegraphed from Lyttelton, and given in our issue of April 2 (p. 516), is thus confirmed. It was not clear at the time of the cable message why the *Discovery* could not get out of the ice, though the relief vessel, the *Morning*, had done so and returned to New Zealand. It is now known, however, that the *Morning* only got within about eight miles of the *Discovery*, and the stores had to be transferred by means of sledges. As the *Discovery* has not returned to Lyttelton, there is little doubt that the expedition has been forced to spend a third winter in the Antarctic. Much additional expense will thus be incurred, and it is estimated that from 12,000*l*. to 20,000*l*. more will be needed to meet it.

THE death is announced of Mr. C. Bartlett, late superintendent of the Zoological Society.

A UNIVERSAL Exposition of Sciences, Arts, and Industries is to be held at Liége in the year 1905.

THE death is announced of M. de Bussy, member of the Institute of France, and well known as a naval engineer.

AN earthquake shock, lasting five seconds, was felt in villages between Worksworth and Derby on Sunday, May 3, at 9.20 p.m.

ACCORDING to a Central News message from San Francisco, dated May 1, a report from San Juan states that the Santa Maria volcano in Guatemala is in a state of active eruption.

THE Louis Pillet prize of the Chemical Society of Paris has been awarded to M. E. Theulier, director of the technical staff and head of the research laboratory of Messrs. Lautier fils, of Grasse.

AN international exhibition of agriculture and horticulture, which the Cercle grand-ducal d'Agriculture et d'Horticulture du Grand-Duché de Luxemburg is organising at Luxemburg on the occasion of the fiftieth anniversary of its foundation, will be held from August 29 to September 7.

IT is announced in *Science* that the Donohoe comet-medals of the Astronomical Society of the Pacific have been awarded to M. Michel Giacobini, of Nice, for his discoveries of unexpected comets on December 2, 1902, and January 15, 1903.

THE proposed electric railway to the summit of Mont Blanc is to be commenced shortly. The municipal authorities of Saint Gervais-les-Bains have accepted the scheme, and have accorded the concession to the French engineers, MM. Deruad and Duportal.

A NOTEWORTHY point in connection with the illuminations of Paris, organised by the reception committee in honour of the King's visit, was the electric incandescent lamps of different colours in the chief streets and avenues and on many large buildings. The effect was very brilliant, and the large crowd of sightseers admired it exceedingly.

THE council of the Society of Arts is prepared to award, under the terms of the Benjamin Shaw Trust, a prize of a gold medal, or twenty pounds, for the best dust-arresting respirator for use in dusty processes and in dangerous trades. Inventors intending to compete should send in specimens of their inventions not later than December 31 to the secretary of the Society of Arts, John Street, Adelphi, London, W.C.

INVITATION cards in the name of the president of the Institution of Electrical Engineers are being issued to members of the Institution for a concert to be given at the Royal Albert Hall on the evening of Thursday, June 11, on the occasion of the International Telegraph Conference. The annual conversazione of the Institution will be held at the Natural History Museum on the evening of Tuesday, June 23. This date has been selected as one on which it will be possible for the members of the International Telegraph Conference to be present.

ON Tuesday next, May 12, Prof. G. H. Darwin delivers the first of two lectures at the Royal Institution on "The Astronomical Influence of the Tides," and on Thursday, May 14, Prof. S. H. Vines begins a course of two lectures on "Proteid-Digestion in Plants." The Friday evening discourse on May 15 will be delivered by Dr. D. H. Scott on the "Origin of Seed Bearing Plants."

THE new Johnston Laboratory at University College, Liverpool, is to be opened by Mr. Walter Long, M.P., President of the Local Government Board, on Saturday, May 9. Many distinguished men of science have expressed their intention to be present at the ceremony. On Monday, May 11, a conference on tropical sanitation will be held in the college.

THE Manchester Literary and Philosophical Society will shortly celebrate the centenary of Dalton's enunciation of the atomic theory. On May 19 Prof. F. W. Clarke, of the Columbia University, Washington, will deliver a lecture on the evolution and philosophy of the theory. Arrangements are also being made for a conversazione at Owens College, and exhibition of Dalton manuscripts, portraits, and other records.

REUTER reports that if within a short time no ship from the Falkland Islands arrives at Montevideo or Buenos Ayres with news of the Nordenskjöld Antarctic expedition, an expedition to relieve Nordenskjöld will be equipped at Stockholm immediately, and should no intelligence of the explorer have come to hand in the meantime, will leave on September 1 for the South Shetland Islands, where it should arrive about the middle of November. The funds required for the relief expedition have already been secured.

A GREAT rock slide occurred on the morning of April 29 at Frank, a small mining town on the Canadian Pacific Railway in the Rocky Mountains, and in Alberta Territory. A telegram from Sir Wilfrid Laurier states that the whole east end of Turtle Mountain from the mouth of Frank Mine slid into the valley and blocked it entirely. The railway was covered with débris for a mile and a half east of Frank. The landslip gave rise to great clouds of dust, which were at first thought to be due to a volcanic eruption, and was reported as such, but this conclusion was entirely unfounded.

CAPTAIN SVERDRUP gave an account of his expedition to the Arctic region in 1898 to 1902 before the Royal Scottish Geographical Society on Monday night, and was presented with the gold medal of the Society in recognition of his achievements. Sheriff Guthrie, who presided, prefaced the address with an appeal on behalf of the Scottish Antarctic expedition under Mr. W. S. Bruce. The leader hoped to be engaged in his work for two years, and funds for the first year are still short by 2250*l*., while for the whole expedition a sum of 10,000*l*. is wanted.

THE Government of India is endeavouring to bring into being the Tata institution for scientific teaching and research at Bangalore. The *Daily Mail* states that the Government has just addressed the Bombay Administration, offering to increase the grant so as to raise the total annual income of the institute to 15,000*l*., conditionally on the Mysore durbars carrying out its proposal that they should assist. Lord Curzon hopes that Mr. Tata will now expedite his arrangements so as to enable legislation for the constitution of the institute to proceed.

IN the article on standardisation which appeared in NATURE of April 23 (p. 587), it is stated that the work of the Engineering Standards Committee was started two years ago at the suggestion of the Institution of Mechanical Engineers. Mr. Leslie S. Robertson, the secretary of the committee, writes to point out that the committee was formed in pursuance of a resolution of the council of the Institution of *Civil* Engineers. We are glad to make this correction, both for the sake of historical accuracy and because the fact was well known to the writer of the article, who inadvertently named the wrong institution.

M. E. DUPORCQ (Ingénieur des télégraphes), whose death was announced recently (p. 589), was general secretary of the Mathematical Congress at Paris in 1900, and worked hard to make it a success. He was also a vice-secretary of the Mathematical Society of France, and editor of the *Nouvelles Annales*, where most of his mathematical contributions are to be found. These were chiefly in the region of elementary pure mathematics, and he was also a deviser of mathematical problems of the style of Prof. Wolstenholme.

PROF. GEORGE E. HALE has informed *Science* that Miss Helen E. Snow, of Chicago, has provided for the reconstruction of the cœlostat reflecting telescope of the Yerkes Observatory as a memorial to her father. The telescope will be provided with solar and stellar spectrographs, spectroheliographs and other important accessories. The cœlostat reflector which the new telescope is to replace was seriously injured by fire last December, giving rise to erroneous but widespread statements that the main building of the Yerkes Observatory, as well as the 40-inch refractor, had been destroyed.

WE are requested to announce that a representative committee has been formed for the purpose of raising a memorial to the late Sir Henry Bessemer. The remarkable industrial development of the world in recent years is largely due to the metallurgical process which bears the name of Bessemer, and it has long been felt that his life's work should be suitably commemorated in the centre of the British Empire. The objects of the memorial are, first, the erection (and, if necessary, the endowment) of metallurgical teaching and research works in connection with the University of London, equipped for the testing of ores and metallurgical products by modern methods, and for the investigation of new methods and processes; and, second, the foundation of international scholarships for post-graduate courses in practical work in connection with proposals now under the consideration of the Board of Education. The committee is thoroughly representative, and among the men of science upon it are Sir William Abney, K.C.B., F.R.S., Sir John Wolfe Barry, K.C.B., F.R.S., Dr. C. Le Neve Foster, F.R.S., Prof. A. K. Huntingdon, Sir Arthur Rücker, F.R.S., and Sir H. Trueman Wood. A meeting to inaugurate the fund will be held at the Mansion House on Monday, June 29 next, particulars of which will be published later. All communications should be addressed to the secretary, Mr. Charles McDermid, Bessemer Memorial Fund, Salisbury House, London, E.C.

BY the death of Mr. Osler, which occurred on April 26 at his residence, South Bank, Edgbaston, Birmingham, at the age of ninety-five, meteorological science has lost another of its distinguished pioneers. His principal works in this science were contributed to the *Proceedings* of the British Association, and to the *Proceedings* of the Literary and Philosophical Society of Birmingham, between the years 1836 and 1858. He was perhaps best known by his invention of a self-recording direction and pressure anemometer and rain-gauge; one of these instruments was erected at the Philosophical Institute at Birmingham, and a discussion of the observations obtained by it during the years 1839 and 1840 was published in the *Proceedings* of the British Association. Another instrument was erected at the Liverpool Observatory in 1851, and a summary of the records for 1852–5 was published in the latter year. From a report recently received from that observatory, we find that his combined anemometer and rain-gauge is still in use, and continues to give entire satisfaction. In recognition of his researches in this branch of science he was elected a fellow of the Royal Society in 1855. In his earlier years he was actively engaged in the development of the glass industry in Birmingham.

M. PAUL DU CHAILLU, the African explorer and discoverer of the gorilla, died at St. Petersburg on April 30. Paul

Belloni du Chaillu was born in 1835, and at an early age he went to live in the French colony of Senegambia, where his father was a trader. There he acquired a knowledge of languages and modes of life of the tribes, devoting much attention to natural history. At the age of seventeen he went to the United States, where he naturalised himself, but in 1855 he sailed for West Africa again, and spent four years in the interior unaccompanied by any white men, traversing a distance of more than 8000 miles on foot in the equatorial region. The results were embodied in the most important of his works, "Explorations and Adventures in Equatorial Africa" (1861). He returned also with many specimens, some of which were acquired by the British Museum. The work provoked much controversy, and his gorilla and cannibal stories, in particular, were widely discredited; but the general truth of his narrative was afterwards substantiated, both as regards the river systems of the Continent, its equatorial population, and its zoological characteristics. In 1862–65 Du Chaillu revisited West Africa, and afterwards published an account of the expedition in a volume under the title of "A Journey to Ashango-land" (1867). Since then he had made journeys in Sweden, Lapland, and Finland, and written numerous works, the chief being "Stories of the Gorilla Country," "Wild Life under the Equator," "Lost in the Jungle," "The Country of the Dwarfs," "The Land of the Midnight Sun," and "The Age of the Vikings," in which he contended that the origin of the English race was Scandinavian. He was also the author of other works.

REFERRING to Mr. G. Henschel's letter in last week's NATURE (p. 610) on complementary singing by bullfinch and canary, Mr. J. R. Paul writes from Alcluith, Dumbarton, to say that he put a red-pole in a cage hung between the cages of two canaries. After a time the bird dropped the brisk "tweet, tweet" of the finches, and began to imitate the canaries' song. His song is now an almost perfect copy of the canaries' notes, and his own particular note is quite lost. Moreover, Mr. Paul adds that a pair of little green parraquets are also learning the canaries' song. "Within a very few days of their arrival they began to try 'notes,' and already the imitation is laughably correct, the 'squawky,' parrot-like voice making the song only the more ludicrous."

THE first scientific meeting of the Challenger Society for the Promotion of the Study of Oceanic Zoology and Botany was held on April 29, Dr. R. N. Wolfenden in the chair. In a paper on bipolarity, Dr. G. H. Fowler cited recent memoirs to show that, in spite of a good deal of destructive criticism, a *prima facie* case had been made out for a marked similarity (amounting in some instances to specific identity) between the two sub-Polar faunas. Dr. Wolfenden gave a preliminary account of the Copepoda collected by Mr. J. S. Gardiner in the Maldive Archipelago. More than ninety species had been already identified, of which some sixteen were new. Mr. E. W. L. Holt exhibited and made remarks on a new Gnathophausia from deep water. A committee was appointed to inquire whether it will be possible for the Society to undertake a card catalogue for oceanic work.

THE monthly *Bulletin* published by the Philippine Weather Bureau under the direction of the Rev. J. Algué, S.J., contains much valuable information relating to the meteorology and microseismic movements of the Archipelago; the tables include meteorological data deduced from hourly observations made at the Manila Observatory, and rainfall and temperature data at a considerable number of stations. The last *Bulletin* we have received, for November, 1902, gives an account and the track of a typhoon which occurred between November 7 and 12. This typhoon was one of the most rapid that has been experienced, and its speed did not decrease until it reached the Asiatic continent. The map shows that at noon on November 7 it was near the meridian of 135° east, and that twenty-four hours later it had already reached 122° east longitude, and that it entered Luzon during the afternoon of that day. It speaks well for the efficiency of the forecasting department of the observatory that it was able to give timely warning of the approach of the storm to the provinces threatened.

THE Meteorological Office pilot chart for May shows that there are immense quantities of icebergs and field-ice about the Newfoundland banks, so much, indeed, that the steamship owners have been compelled to order their commanders to disregard the international steamer routes, and keep about sixty miles to the southward, so as to endeavour to keep clear of the danger. A number of bergs have been sighted southward of the 41st parallel, beyond the southern point of the Great Bank, and they extend thence northward in vast numbers up the edge of the bank to about the 50th parallel, and no doubt far beyond, while they are scattered as far eastward as the 40th meridian and westward to the 55th meridian. In addition quantities of field-ice, drifting out of the St. Lawrence by Cabot Strait, render navigation in the neighbourhood of Cape Breton and the south of Newfoundland dangerous. It is many years since there was so much ice in the neighbourhood.

NEGOTIATIONS are in progress with the Danish Government for establishing wireless communication to Iceland by the Marconi system. A provisional agreement has been made between the Marconi Co. and a Danish association by which the latter has the option of carrying out the project; it has not yet been decided whether the communication shall be direct between Iceland, the Faröe Islands and Jutland, or between the islands and Scotland.

THE full text of the Government Bill "to facilitate the introduction and use of electrical power on railways," which was read for a first time last month, has now been printed. The chief effect of the Bill is to give the Board of Trade power to make orders authorising railway companies to use electricity as motive power, and to generate such power or make agreements for its supply. There are several other clauses in the Bill relating to provisions which would be necessary in the case of a railway company changing over partly or wholly to electrical working. The Bill, as it facilitates acquiring the necessary powers for electrical working by doing away with the necessity for introducing a private Bill, can only help forward progress in this direction. The Government is certainly to be congratulated on having, for once in a way, recognised the probable developments of science before it is too late, and we hope that the Bill will soon become law, and that the railway companies will avail themselves of its provisions.

SOME interesting evidence was given before the departmental committee on electricity in mines by Mr. Selby Bigge, especially in relation to the position of this country in comparison with America and continental countries. Mr. Bigge stated that he thought this country was very much behindhand, not only in the application of electricity to mining, but in the manufacture of electrical machinery generally. This he attributed partly to the restrictive nature of our legislation, and partly to the lack of scientific training on the part of the managers and others in authority. He instanced numbers of examples of electrical mining in-

stallations on the Continent, laying special stress on the application of three-phase working and the use of high voltages which this system permitted; he even went so far as to say that, paradoxical as he might seem, the higher voltages were probably safer, as the workmen, knowing that any tampering with the mains meant certain death, left them severely alone. For the actual machinery, 500 to 700 volts was a suitable pressure, but 1000 to 3000 volts might be used with advantage for transmission for considerable distances into the mines. Other evidence of an interesting nature was given before the committee, which is still sitting.

OFFICIAL statistics have on several occasions been collected as to the number of horses and other beasts of burden in Italy, but statistics regarding educational matters appear to be few and far between. The only records of the total attendances in Italian schools or colleges under the control of public or religious bodies refer to the year 1870. For private boys' schools results were collected from 1879, and for girls' schools from 1887, but in no case does information extend beyond 1894. Prof. Amato Amati, writing in the Lombardy *Rendiconti*, now asks for an official census of the private schools and educational institutions of Italy.

VARIOUS experimenters have obtained interference between light-waves with a difference of path reaching in one case as much as 790,000 wave-lengths. Profs. Lummer and Gehrcke now describe experiments in the *Verhandlungen* of the German Physical Society, in which interference phenomena were obtained after nine reflections at the surfaces of a uniform plate, representing a difference of path of 2,600,000 wave-lengths, and they draw the conclusion that among the particles of vapour in the mercury arc used as the source of light, the greater portion send out light capable of producing interference for a longer time than the interval (less than 10^{-8} of a second) in which $2\frac{1}{2}$ million waves are emitted.

THE importance of a convenient, accurate, and at the same time readily understood designation of musical notes in connection with the study of audition and partial deafness forms the subject of a paper by Sir W. R. Gowers, F.R.S., in the *Review of Neurology and Psychiatry* for April. At present there is no uniformity of notation, and the notation adopted by Helmholtz was merely an old and inconvenient notation used in organ construction. The present writer proposes to use C to denote the "middle C" (frequency 264), to use C^1, C^2, C^3 to denote the successive octaves *above*, and to use C_1, C_2, C_3 to denote the successive octaves *below* middle C, each octave extending to the B above.

IN describing the brain of the walrus, Mr. P. A. Fish (*Proc.* U.S. Nat. Mus., No. 1325) shows that the general plan of the fissures corresponds to that obtaining in Carnivora generally, and more especially seals.

THE Natural History Branch of the British Museum has received from Lord Crawford a small but interesting series of birds' skins collected by Mr. M. J. Nicholl on St. Paul and Noronha Islands, off the Brazilian coast. The only specimens from the latter island previously in the collection were obtained by Dr. H. N. Ridley in 1886.

IN vol. iii., part iii., of the *Annals* of the S. African Museum, Mr. G. A. Boulenger describes six new forms of perch-like fishes from the Natal coast. Recent issues of the *Proc.* U.S. Nat. Mus. contain papers on the band-fishes (Cepolidæ) and loaches (Cobitidæ) of Japan, by Messrs. Jordan and Fowler.

IN the course of a series of notes on the ornithology of Norfolk for 1902, published in the April number of the *Zoologist*, Mr. J. H. Gurney directs attention to the great migration of rooks and other members of the crow family which took place on the east coast during October of last year. The greater number of the immigrants were rooks, and the movement extended at least as far as Lincolnshire. Several rare birds are recorded as stragglers. Mr. Gurney adds that there is no good news to record of the great bustards which were turned down at Brandon in 1900. Of the original fifteen, only a single pair now remain; the hen laid a couple of eggs, which were incubated for six weeks without a successful result.

WE have received from Prof. W. C. M'Intosh a copy of a pamphlet on British fisheries' investigations and the international scheme. After referring to past and present investigations in connection with British fisheries, the author discusses the international scheme for the systematic biological survey of the North Sea, to which allusion has recently been made in our columns, urging that if the British Government resolves to participate in the scheme, attention should be concentrated on the habits and development of fishes and their food-supplies to the exclusion of subjects connected with hydrography. In regard to the supposed deterioration of our fisheries, Prof. M'Intosh is an optimist, remarking that "There is no fear of the extinction of any species, especially of those important to man. Furthermore, fishes have abounded in the primæval as in the modern seas, although the ravages of the gigantic reptilian and other fish-destroyers—which in some instances were distributed over the whole expanse of the ocean—could not have been less than even the far-reaching efforts of man. In neither period has extinction ensued from the prevailing agencies, nor is it likely to take place under these conditions in the future."

AN account of the structure and properties of a leguminous liane, *Derris uliginosa*, the leaves of which have been used as a fish poison by Fijian islanders, has been received from the Wellcome Research Laboratories. A description of the anatomy of the stem is furnished by Mr. Perrédès, from which it appears that irregular secondary vascular structures arise in the cortex. As a result of chemical investigation, Dr. Power discovered a considerable amount of tannin and various resinous substances. The toxic action is attributed to a constituent of that part of the resin which is soluble in chloroform, and not to the tannin.

THE progress of the German East African colony may be studied in the reports presented by the officers in charge of districts, which are embodied in the *Berichte* issued from Dar-es-Salâm. The native food resources are matama, maize, manioc, and in some parts bananas. Owing to the risks of failure of the three first, the natives have been encouraged to take up the cultivation of rice and sweet potatoes. As a source of revenue extensive plantations of coffee have been started by German companies, and on a smaller scale the cultivation of coco-palms, agave and ceara rubber is being extended with promising results.

OF the papers read before the American Society for Plant Morphology and Physiology, two contributed by Dr. E. F. Smith refer to bacterial diseases attacking Japanese plum trees and sweet corn, in both of which cases the author concludes that infection takes place through the stomata. A paper by Prof. Duggar traces the inconsistency of the osmotic action of certain salts on marine algæ to their toxic action, and potassium salts were found to be more

poisonous than the salts of calcium or magnesium. Prof. Jeffrey outlines an anatomical clue to the phylogeny of the monocotyledons which would derive them from dicotyledons. A suggestive paper by Prof. Toumey discusses the initial root system of tree seedlings.

THE latest addition to the useful series of short scientific memoirs published in Paris by M. C. Naud under the name *Scientia* is by Dr. L. Décombe, and is entitled "La Compressibilité des Gaz Réels." This is the twenty-first volume in the series dealing with physical and mathematical subjects.

THE Cambridge University Press has published the second part of vol. ii. of the "Reports of the Cambridge Anthropological Expedition to Torres Straits," which deals with physiology and psychology. The fasciculus contains sections by Mr. Charles S. Myers on hearing, smell, taste and reaction-times, and by Mr. W. McDougall on cutaneous sensations, muscular sense, and variations of blood-pressure.

THE decision of the Government to continue the present temporary Vaccination Act for one year has met with the approval of conscientious objectors, whose case Mr. Alexander Paul appears to take up in his little book, "The Vaccination Problem in 1903, and the Impracticability of Compulsion," recently published by Messrs. P. S. King and Son. The book should be useful in making clear the position of the objectors, so that the difficulties they put forward can be satisfactorily met when occasion requires it.

THE Orient-Pacific Line have published their pleasure cruise arrangements for the forthcoming Norway season. Three steamers will be employed, viz. the *Orient*, the *Cuzco* and the *Ophir*. The cruises begin on June 11, and vary in length from twenty to twenty-eight days. In addition to the attractions of Norwegian scenery and the Midnight Sun, the programme includes a visit to the glaciers of Spitsbergen with a prospect of seeing the Polar pack.

MR. A. R. HINKS writes in the *Monthly Review* for May on the evidence for life on Mars, and his article is illustrated by two maps of the canals or channels observed by Schiaparelli. The article is largely taken up with an account of Mr. Percival Lowell's observations of Mars at Flagstaff, in Arizona, and the conclusions drawn by Mr. Lowell, following a suggestion of Schiaparelli, as to the existence on Mars of a great irrigation system.

THE report of the council of the Hampstead Scientific Society for the year 1902 shows that the association continues its commendable activity. Among the lectures organised by the Society during the year may be mentioned those of Prof. Boyd Dawkins, F.R.S., on the forest primeval of the Coal-measures; Mrs. Dr. Bryant, on bees as builders of the honeycomb and otherwise; and Dr. Shenton, on medical applications of Röntgen rays. But much of the useful work of the Society is accomplished in sectional meetings, which are held in connection with the astronomical, the natural history, and the photographic sections two or three times a month. The example set by the Hampstead Society might with advantage be more widely copied.

CONSIDERABLE evidence is being accumulated at the present time which is apparently strongly antagonistic to the view that electrically charged ions are the factors which are directly active in all cases of chemical change. In the March number of the *Journal of Physical Chemistry*, Mr. H. E. Patten gives an account of experiments on the interaction of metals and hydrochloric acid in various perfectly anhydrous solvents. The solvents employed were benzene, chloroform, tin and silicon tetrachlorides, phosphorus and arsenic trichlorides, antimony pentachloride, sulphur monochloride, and thionylchloride. These solvents had a smaller conductivity than air, and yet zinc was in all cases directly acted upon by the acid.

AN interesting study of the modifications of acetaldehyde is the subject of a paper by R. Hollmann in the *Zeitschrift für physikalische Chemie*. Experimental data are given which show clearly the relationships existing between acetaldehyde and paraldehyde for temperatures ranging from $-100°$ C. to $300°$ C. Of special interest are the observations relating to the composition of the liquid substance in its natural state of equilibrium. At the melting point ($6·75°$ C.) the liquid consists of 88·3 per cent. of molecules of paraldehyde, whilst at the boiling point ($41·6°$ C.) the molecular proportion is 53·4, and at the critical temperature ($217°$ C.) only 11 per cent.

THE additions to the Zoological Society's Gardens during the past week include a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Mr. H. R. Harger; a Springbok (*Gazella euchore*) from South Africa, two Feline Dourocoulis (*Nyctipithecus vociferans*) from Southern Brazil, two Violet-necked Cassowaries (*Casuarius violicollis*) from the Aru Islands, four White-eared Bulbuls (*Pycnonotus leucotis*), an Indian Python (*Python molurus*), four Saccobranchs (*Saccobranchus fossilis*) from India, three Grey-breasted Bullfinches (*Pyrrhula griseiventris*) from Japan, three Mocassin Snakes (*Tropidonotus fasciatus*) from North America, five Red-spotted Lizards (*Eremias rubropunctata*) from Egypt, a Delalande's Gecko (*Tarentola delalandii*) from West Africa, deposited; a Diamond Snake (*Python spilotes*), three Brush Turkeys (*Talegalla lathami*) from Australia, purchased; an Axis Deer (*Cervus axis*), eight American Timber Wolves (*Canis occidentalis*), two Crab-eating Raccoons (*Procyon cancrivorus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A telegram received from the Kiel Centralstelle informs us that Mr. Grigg, observing at Mr. Tebbutt's observatory, Windsor, New South Wales, discovered a new comet on April 17. The position of this object at 6h. 44m. 2s. (M.T. Windsor) on April 27 was:—

R.A. = 4h. 3m. 24s.
Dec. = $16° 23' 25''$ south.

The daily movement in R.A. is $+1° 26'$, and in declination $+0° 27'$; the announcement says nothing about the comet's brightness.

The above position is a little s.f. of γ Eridani.

NOVA GEMINORUM.—A telegram received from Prof. E. C. Pickering on April 22, published in No. 3864 of the *Astronomische Nachrichten*, states that "the light of Nova Geminorum is increasing."

THE PARTIAL ECLIPSE OF THE MOON ON APRIL 11.—The most striking feature of this eclipse was the blackness of the eclipsed surface, for it was not possible to see any of the details on that portion of the surface which was covered by the shadow. In a paper published in No. 16 (1903) of the *Comptes rendus*, M. Montangerand describes the results of the attempts he made to photograph that portion of the lunar surface eclipsed by the earth's shadow.

Using the astrographic-chart telescope and Lumière plates, and giving an exposure of one second to each plate, he obtained eleven negatives, two of which, Nos. vii. (Lumière "blue") and ix. (Lumière panchromatic), show the contour of the eclipsed moon, but no surface details.

The visual observations corroborate the photographs in showing that at this eclipse the shadow was especially black, so that no details of the eclipsed surface could either be seen or photographed. This result differs greatly from that recorded for the eclipses of December, 1898, and December, 1899, when the eclipsed surface was plainly visible and of a marked ruddy colour.

THE OCCURRENCE OF SPARK LINES IN ARC SPECTRA.—In a paper which recently appeared in the *Sitzungsberichte der K. Akademie zu Berlin* (January 22), Messrs. J. Hartmann and G. Eberhard give the results of a number of experiments they have made in order to determine under what conditions various lines, usually associated with spark spectra, may appear in the spectrum of the arc.

In the cases of magnesium and silicon—which are so important when considering stellar spectra—the authors found that when the arc was produced under water, using metallic poles, the magnesium line at λ 4481 and the silicon lines at $\lambda\lambda$ 4128 and 4131 were produced, although all three are usually called "spark" lines. In the case of zinc, the "spark" lines at $\lambda\lambda$ 4912 and 4925 were obtained under similar conditions.

The authors have also photographed the spectra of these metals when the arc was enclosed in an atmosphere of hydrogen, and again, under these conditions, the "spark" lines appeared. From this similarity of the results Messrs. Hartmann and Eberhard arrive at the conclusion that, when the arc is struck under water, it immediately becomes surrounded by an atmosphere of hydrogen, produced by the decomposition of the water, and so the same results under the two different primary conditions are obtained (*Astronomische Nachrichten,* No. 3858).

FOUR STARS WITH VARIABLE RADIAL VELOCITIES.—In *Bulletin* No. 31 of the Lick Observatory, Mr. H. M. Reese announces the discovery of four more stars having variable velocities in the line of sight; they are as follows:—

υ Andromedae.—Plates secured on October 8 and November 5, 1902, and January 14, 1903, show velocities of −17 km., −76 km., and +49 km. respectively. The spectrum shows few lines, and the hydrogen lines are broad, but the helium lines are fine and easily measurable.

π^4 Orionis.—The plates obtained on October 6, 1902, January 4 and January 12, 1903, indicate velocities of +43 km., ±0 km., and +6 km. respectively, the spectrum being similar to υ Andromedæ.

σ Geminorum.—Velocities of +74 km., +12 km., +9 km. and +69 km. are indicated by negatives obtained on March 16, 1902, January 12, 13, and February 15, 1903, respectively. The lines, though numerous, are rather hazy, but they give trustworthy results.

ι Argus.—The variable velocity of this star was discovered by Prof. Campbell from the comparison of a plate obtained on February 21, 1898, with previous measures. A series of seven photographs obtained between February 23, 1897, and February 18, 1902, shows a range of velocity from +41·9 km. to +50·3 km.

The photographs mentioned above have been obtained with the Mills spectrograph, and measured by Messrs. Reese and Curtis. Mr. Reese also announces that the star ϕ^2 Orionis is an especially interesting object on account of its great radial velocity, plates obtained on October 28, November 24, and December 30, 1902, indicating velocities of +94 km., +102 km., and +96 km. respectively. The range of 8 km. may not be taken as indicating a variable velocity for this star, for although the photographs show fairly good lines, the second one—in which the variation appears—was very much under-exposed.

THE HARVARD MERIDIAN PHOTOMETER OBSERVATIONS.—Part ii. vol. xliv. of the Harvard College Observatory *Annals* is devoted to a description of the reduction of the observations made with the meridian photometer during the years 1892–98. The editor, Prof. E. C. Pickering, gives a detailed description of the meridian photometer and the methods pursued in making the observations. This description is followed by tables giving the results of the observations of Harvard photometer and A.G. catalogue stars made during the period named above, each table being followed by voluminous notes as to the peculiarities of the observed objects and the observing conditions.

ENGINEERING EDUCATION ABROAD.

THE conditions governing the competition among the great manufacturing countries for the markets of the world have, during the last thirty years, undergone profound modification. At the beginning of the latter half of last century British manufacturers held an unique position which secured for them what was practically the monopoly in some departments of the world's trade. The reasons for this fortunate position are too well known to require elaborate recapitulation. It is enough to remember that while other countries were on one hand engaged in war and on the other in maturing a stable and enduring constitution, Britain was establishing flourishing manufacturing centres, which, with the assistance of her possession of coal and iron, supplemented as it was by the natural endowments of her citizens so far as perseverance and inventiveness were concerned, resulted in her becoming the world's workshop. In no direction was this supremacy more pronounced than in the several branches of the engineering trades. But since then great changes have taken place. By carefully laid plans and persistent effort, other countries have succeeded in overcoming their disadvantages, and as a result of the provisions they have made for the education of their young men in scientific technology, the British manufacturer has now to reckon with formidable German and American competitors.

The changed conditions have been made the subject of study by several authorities in this country, one of the most recent being Prof. W. E. Dalby, who has studied the question of the education provided for engineers in America, Germany and Switzerland. The opportunity which his commission from Mr. Yarrow to report on the training of engineers in other countries has given Prof. Dalby make the recent papers read by him before the Institution of Naval Engineers and the Institution of Mechanical Engineers of exceptional value, and it is much to be hoped that the following facts from his papers, and the lessons to be drawn from them, may have a good effect in convincing our manufacturers and educational authorities that the higher education of those engaged in industrial pursuits has a direct and immediate effect on success in the struggle for commercial supremacy.

The paper read before the Institution of Naval Architects was concerned only with the education of engineers in the United States; that before the Institution of Mechanical Engineers included a study of the question in Germany and Switzerland also. It will be most convenient to take these countries in order. Beginning with the United States, the nature of the technical education in the best colleges may first be considered, and then the relation between the employers and the technically trained men graduating from these colleges.

America.—A good idea of the aims of the technical colleges of America may be gathered from the words of one of the chief founders of the Massachusetts Institute of Technology of Boston, who laid it down that the most truly practical education, even in an industrial point of view, is one founded in the thorough knowledge of scientific principles, which unites with habits of close observation and exact reasoning a large general cultivation. The highest grade of scientific culture is not too high a preparation for the labours of the mechanic and manufacturer, and there are in the history of social progress ample proofs that the abstract studies and researches of the philosopher are often the most beneficent sources of practical discovery and improvement.

Inspired by such enlightened views of technical education, it is not surprising that there has been a steady increase in the number of engineering students in the chief American colleges. The first table on p. 18 gives an idea of the growth of their engineering departments.

At Cornell University students of mechanical engineering and the allied branches do their work at Sibley College; there is a separate building for civil engineering and architecture. Sibley College is divided into eight departments, viz. mechanical engineering, mechanical laboratory instruction, electrical engineering, mechanic arts (workshops), industrial drawing and art, machine design, graduate schools of marine engineering, and the graduate school of railway mechanical engineering.

Showing Numbers of Students in Engineering in Certain Colleges.

	YALE. Civil, Mechanical, Electrical, Mining and Sanitary Eng. Students in the Sheffield Scientific School.	CORNELL. Civil, Mechanical and Electrical Students.	MASS. INST. Civil, Mechanical, Electrical and Mining Students.
1895–96	209	617	357
1896–97	174	623	352
1897–98	153	645	356
1898–99	166	686	347
1899–00	162	774	356
1900–01	163	844	372

The staff consists of thirty-six teachers and instructors, and this number includes six professors and four assistant professors, and eight non-resident lecturers. The staff is inadequate at the present to deal with the numbers of students in the college.

A great feature of this institution is its workshops. Here instruction is given in pattern-making, moulding, forging, fitting and turning, and the work done in them is real. All students in the college pass through the same course during the first three years. They may specialise in the fourth year in steam, marine, railway or electrical engineering with specialists in those subjects.

Admission to the course in the American college is by examination. To enter Cornell a student must be sixteen years of age, and to enter the Massachusetts Institute seventeen. The standard of examination is such that a youth from a good high school can pass. There is no freedom left to the student regarding his course of studies when once he has chosen his department. Examinations are frequent, and promotion from one year to another depends upon the result of them. The courses are really a carefully-thought-out and elaborately organised species of educational drill. As a general rule a man must go through with it or fall out.

At the Massachusetts Institute the courses are so arranged that a student can do his work in forty-eight hours per week. Half of this time is given to lectures, &c., at the college, the other half is assumed to be spent in private study. The same method appears to be in operation at Cornell, Harvard and Yale. An analysis of the courses shows what is understood by a technical education in the States; it is really four years of continuous hard work at a college equipped with engineering laboratories and workshops, and with all the educational apparatus for giving a scientific education.

It is interesting to note the attitude of employers in the United States to the men who study in the way just described in these American colleges. A point in which American practice is remarkably different from ours is that age is no limit to a man who wants to get practical work in the shops, providing he is a college graduate. Employers might not take on an apprentice after twenty-one years of age if he were not a graduate. College graduates in America never find that, whilst learning the scientific principles of their profession, they have grown too old to enter the workshops to learn the practical part. The general opinion seems to be that the educated man picks up his practice much quicker and more intelligently than the younger man with only an ordinary education. Generally speaking, the attitude of the American employer towards these graduates is one of distinct encouragement, and of advantage to both. The employer gets the advantage of a trained intellect, the employee gets the advantage of his employer's shops and business experience. The American employer keeps an "open door" for the technically trained man, whilst with us in England the door is too often closed by rules regarding age and the like, and the would-be apprentice not having sufficient means to pay a premium in addition to the amount he has already paid for his education. In cases where college graduates are taken on in England, they are, as a rule, expected to go through the same course in the shops as a boy entering straight from school. The Americans are more yielding in this respect, and do not insist upon the drudgery of the first few years.

Germany.—The Berlin Technical High School at Charlottenburg is a State institution, and its object is to give a specialised training in industrial subjects founded on a preliminary scientific education. The course, lasting four years, begins with scientific subjects, and gradually becomes more technical until in the fourth year all the subjects are specialised. German subjects are admitted to the school on the production of a "maturity certificate" from a German gymnasium or a Prussian real-gymnasium. The education given at the two kinds of schools corresponds very roughly with that given in the classical and modern courses of our public schools. The maturity certificate is obtained at the end of a nine years' course. Those admitted by means of this certificate are styled *Students*.

Persons who cannot obtain or have not obtained this certificate can be admitted on school certificates of a lower value, but for the departments of architecture, civil and mechanical engineering and naval architecture must in addition show that they have worked for at least one year in some works. Those entering in this way are styled *Hospitanten*. The school has recently been given the status of a university.

As an instructive indication of the importance attached to higher technical education in Germany, the tables which have been drawn up by Prof. Dalby showing the numbers of students and teachers at the Charlottenburg institution may be given:—

Students of Various Grades in Attendance for the Winter Half-Year, 1902–3.

	Students.	Hospitanten.	Total.
1. Architecture	477	262	739
2. Civil Engineering	647	42	689
3. Mechanical Engineering:			
Specialising in Mechanical Engineering	1319	180	1499
Specialising in Electrical Engineering	270	51	321
4. Naval Architecture:			
Specialising in Naval Architecture	241	18	259
Specialising in Marine Engineering	106	17	123

Honorary Assistants	53	33	67	9	10	27
Total	89	56	115	21	55	66

Expressed briefly, there are 4378 students of all kinds and 402 members of the teaching staff.

A distinguishing characteristic of the Berlin Technical High School is the right maintained by the students to choose their own courses of study. This freedom is common to German universities, and it follows that the educational authorities can only suggest courses of study, leaving the students free to follow their suggestions completely, or partially, or not at all. Nevertheless, very complete and elaborate courses have been arranged, and as a rule are followed by the students.

There is no attempt to teach workshop practice. Laboratory teaching is confined to the engine laboratory and the electrical laboratory, with a little practice in testing materials at the neighbouring Government testing establishment (Königliche mechanische-technische Versuchanstalt).

The most striking feature of the course is the relatively large amount of time devoted to machine construction, including machine drawing, graphic statics, descriptive geometry, and the lectures connected with the various forms of machines, in which exercises in the drawing office are given. Prof. Riedler, who is at the head of this department, carries on a large engineering practice in the building, employing between twenty and thirty draughtsmen. The majority of these men take part in teaching the subject, so that mechanical drawing and machine design are taught by practical draughtsmen engaged for the greater part of their time in actual designing. No better method than this could be devised, because to all intents and purposes the students are working under actual drawing-office conditions.

A student passing through this course has a large amount of drawing-office practice of an advanced character, but very little practical work. Whether this kind of training is the best is a matter of opinion, but Prof. Dalby thinks a course which makes less claim on the students' time for college work and allows more for practical work would, on the average, in the long run produce better engineers.

Switzerland.—The Polytechnic at Zurich is a State institution designed to give a specialised training in industrial subjects. The course lasts four years. Students are admitted by examination at eighteen years of age. A "maturity certificate" from a Swiss school is taken in lieu of an examination, or a student may be excused part of the entrance examination by presenting certain school certificates. During 1901–2, there were 181 Swiss students of civil engineering, 230 studying mechanical engineering, and 49 taking up architecture, and in addition 249 foreigners in the same departments.

The lectures and exercises as announced in the programme of the several departments are obligatory on the student. In each department, however, the students are allowed a choice in the third year. Once having chosen, they are obliged to follow the plan selected. As at Berlin, no attempt is made to teach workshop practice, but the bulk of the time is given to drawing-office work.

General Remarks.—In all the courses described, a common scientific basis in the first two years develops into widely divergent and specialised branches in the remainder of the course. It should be understood that both in the States and on the Continent many of the specialised lectures are given by men in the full practice of their profession, and who are not regular members of the teaching staff. The best courses in this country are arranged on practically the same basis, but the longest being three years, there is no time to develop the instruction into the specialised branches of engineering.

There is an essential difference in the method of training in America and Germany. In America the course of instruction is very exactly laid down, and the student is compelled to follow it step by step. Slight variations are permitted in the form of options, to use their term, in the later periods of the course. The student gets his degree from the gradually accumulating results of terminal and sessional examinations, ending finally with a thesis.

In Germany the students of their great technical high schools enjoy the freedom peculiar to the university system of that country. No student is compelled to take any special course. For his convenience definite courses are arranged and laid down in the school calendar, but the sequence of lectures therein stated is not binding. The courses are only recommendations, and students may follow them or not as they please. At Zurich the course is partly prescribed, partly selected.

The following table gives a good idea of the nature of the engineering courses in the three countries, the subjects studied, and the relative importance attached to each.

The Percentage Number of Hours' Instruction given in Various Mechanical Engineering Courses.

	Massachusetts Institute.	Cornell.	Berlin Technical High School.	Zurich Polytechnic.
Mathematics	8	5	14·5	19·2
Physics	5	8	6·8	6·0
Chemistry	7	7	1·7	3·0
Applied Mechanics	7	10[1]	22·5	19·5
Mechanism	4	—	8·0	—
Steam-Engine, including Thermodynamics	6	6	4·1	8·0
Mechanical Drawing[2]	26	20	31·0	39·3
Electrical Engineering	2	2	3·4	5·0
Commercial Subjects	2	—	8·0	—
Workshops	14	30	Nil	Nil
French	6	—	"	"
German	3	3	"	"
English	5	—	"	"
Engineering Laboratories	5	9	[3]	[3]
	100	100	100·0	100·0
Approximate Hours	3000	3000	4000	4000
Distributed over	Four Years.	Four Years.	Three Years.	Three Years.

The fourth year of the continental courses is not included, because it is so cut up with examination work. It must not be forgotten, however, that an American student actually receives 3000 hours' instruction; a German or Swiss student is only recommended to attend courses aggregating 4000 hours. Actually he may work just as many hours as he chooses. In brief, the American courses are more practical in character, they include more laboratory training than is recommended in the German course, and devote a large proportion of the course to the teaching of handicraft skill. In Charlottenburg and Zurich no attempt is made to teach handicraft skill, and the bulk of the training is given in the drawing-office, though in addition a considerable amount of time may be given to engine testing.

One thing is certain, the American, German, and Swiss student starts his course with a far better education on which to build than is the case with us. Much time is wasted at colleges here on teaching things which should have been taught at school. Prof. Dalby believes that the great defect of the British system of training engineers is the want of coordination between the colleges and the employers. If the employers will concern themselves with the question, he feels sure their attitude will speedily change.

The general opinion seemed to be that a course arranged so that the winter months are spent at college and the summer months in the works is a desirable one, and one from which good results may be expected. Such an arrangement obviously cannot be worked without the cooperation of the employers. This alternating system must not be regarded as experimental. Our Admiralty have had something very similar in operation for forty years, and the system has produced a famous roll of chief constructors. The Scottish universities lend themselves to the system, and Glasgow students in engineering consistently study in the winter and work in the summer.

[1] Includes Mechanism.
[2] Includes Freehand, Machine Drawing and the lectures connected with Machine Design.
[3] Laboratory courses are taken in addition, but it is difficult to estimate how much is recommended.

AMERICAN SYMBOLISM.

IN 1899 Mrs. Morris K. Jesup generously provided the means for a study of the Arapaho Indians, and Dr. Alfred L. Kroeber was entrusted with the work; his general description of the Arapaho and of their decorative art and symbolism recently published in the *Bulletin* of the American Museum of Natural History (vol. xviii. pp. 1–150, 1902) proves how well he acquitted himself of his task. Dr. Kroeber now has charge of the anthropological department of the University of California, and we may expect much good work from him in the future in this new field.

The Arapaho are typical Plains Indians, and belong to the linguistic stock of the western Algonkins. The fullest and most accurate account of these people has been given by Mr. James Mooney ("Ghost-Dance Religion," *Fourteenth Ann. Rept. Bureau Ethnol.*), and the sketch of their social organisation and life given by Dr. Kroeber is instructive, and to some extent supplements the previous descriptions.

The main value of Dr. Kroeber's memoir consists in the careful analysis of the meaning of a very large number of designs that ornament objects in every-day use, and in the wealth of the accompanying illustrations. The conscientious labour which this implies is deserving of the thanks of fellow-students of decorative art and symbolism.

There is a good deal of latitude in the interpretation of decorative designs employed by different individuals: usually an Indian refuses to interpret the ornamentation on an article belonging to someone else, giving as a reason that he does not know what that particular artist intended to represent. For example, the rhomboid or diamond-shaped symbol may signify the navel, a person, an eye, a lake, a star, life or abundance, a turtle, a buffalo-wallow, a hill or the interior of a tent. All except the first of these significations have also been found attached to very different symbols; thus, a person is also denoted by a small rectangle, a triangle or a square, by a cross, a dot or a line, as well as by rudely realistic designs. A lake may be represented by a square, a trapezoid, a triangle, a pentagon, a circle or other figures. The decorative symbolism is not intended as a means of communication, hence there is no fixed system of symbolism. One person thinks about the significance of his designs, while another considers chiefly their appearance. The former may have two or three interpretations for one symbol or design which are appropriate and coherent; the symbols of the latter will have their most conventional meaning, without much relation to a thought-out scheme. In either case, the Indian never dreams of making a picture that can be recognised by everyone at first sight. These peculiarities can be paralleled in other parts of North America, and, indeed, elsewhere.

A pictograph serves as a means of record or communication, and is normally not decorative; while this art is too decorative to allow of its being read in the same way; yet there is considerable similarity in the symbols used in both systems. Moreover, the significance of a piece of decoration is at times as extended and coherent as that of a pictograph.

Dr. Kroeber insists that the closeness of connection between this decorative symbolism and the religious life of the Indians cannot well be overestimated by a white man. All symbolism, even when decorative and unconnected with any ceremony, tends to be to the Indian a matter of a serious and religious nature. A. C. H.

THE ORIGIN OF NATURAL GAS AND PETROLEUM.

THE volcanic origin of natural gas and petroleum is strongly advocated by Mr. Eugene Coste in a paper read before the Canadian Mining Institute (March 5). The author points to the complete analogy of the products of the oil and gas fields with the products of volcanic solfataric action. These products are water, chloride salts, sulphur, sulphuretted hydrogen, carbonic acid and hydrocarbons. He brings forward facts upon which he bases his view that all the petroleum, natural gas, and bituminous fields or deposits are essentially the products of solfataric volcanic emanations, condensed and held in their passage upward in the porous tanks (sands, limestones, &c.) of all ages from the Archæan to the Quaternary. He instances the occurrence of carbon and hydrocarbons in gneisses and various ancient plutonic rocks. He likewise refers to the dolerite of the Lothians (described by Mr. H. M. Cadell), in which cavities of the rock are filled with a mineral wax not unlike the ozocerite of Galicia. The oil shales through which the igneous rocks have intruded were in Mr. Coste's opinion impregnated by solfataric emanations, for their bituminous character is local, and in proximity to the igneous rocks. Allusion is made to the occurrence of asphalts and oils along the faulted and broken margins of the Gulf of Mexico and Caribbean Sea, the great asphalt deposit of Trinidad filling the crater of an extinct volcano. Again, natural gas and petroleum are associated with mud volcanoes. The author therefore concludes that carbon and hydrocarbons are derived from deep-seated fluid magmas, in which they exist probably in the form of carbides. The "rock pressure" of natural gas is regarded as a remnant of the initial volcanic energy. This has been registered as high as 1525 lb. to the square inch, but is usually between 200 and 1000 lb., and is a constantly decreasing pressure from the time the gas is first used. The theory that artesian water is the cause of the gas pressure is regarded as untenable.

The author points out how generally the diversified "oil phenomena," which include gypsum, sulphur, dolomite, and salt, are met with in American and other oil and gas fields. Disturbed strata and planes of faulting gave access to volcanic emanations which brought up the various products; the rocks were variously impregnated according to the geological and physical conditions of the strata, and the products were sealed up when impervious unbroken strata remained above. In Galicia solid petroleum or ozocerite exists in veins cutting the strata in every direction, the most important being faults. Elsewhere oil occurs in the fractured strata, and such an elusive fluid, pent up under pressure, could not be in its original home. The local and seemingly accidental occurrence of the oil and gas, and even of bituminous shales, are considered by the author to favour his theory, for he observes that the sedimentary strata could not produce from a limited fossiliferous area the quantity of products. Thus, near Baku, in Russia, a small area of not more than eight square miles has now yielded more than 900 million barrels of oil. H. B. W.

SMITHSONIAN REPORT ON SCIENTIFIC WORK.

DR. S. P. LANGLEY, secretary of the Smithsonian Institution, has issued his report on the operations of the Institution during the year ending June 30, 1902, including the work in the United States National Museum, the Bureau of American Ethnology, the International Exchanges, the National Zoological Park, and the Astrophysical Observatory.

Following the precedent of several years, there is given, in the body of the report, a general account of the affairs of the Institution and its bureaus, while an appendix presents more detailed statements by the persons in direct charge of the different branches of the work. Independently of this, the operations of the National Museum are fully treated in a separate volume of the Smithsonian Report, and the Report of the Bureau of American Ethnology constitutes a volume prepared under the supervision of the director of that Bureau.

The following extracts from the report will show that a vast amount of scientific work is being instituted and carried on under the auspices of the Institution.

Hodgkins Fund.—In connection with the administration of the Hodgkins fund, papers recording the advance of specialists along various interesting lines of investigation have been submitted, some of which are now in course of publication.

The report of the research on the spectrum conducted by Dr. Victor Schumann, of Leipzig, has received extensive additions during the year, notably through a detailed description of the ingenious apparatus used in his work. A second grant on behalf of Dr. Schumann has been approved during the year, and it is interesting to know that

Harvard University, recognising the value of his work, has also awarded him a grant. The new Physical Institute of the Royal Academy of Sciences in Leipzig has likewise aided this research by placing laboratory room at the disposal of Dr. Schumann, who, it is hoped, will be able in the near future to secure still more complete results from his painstaking experiments in vacuum spectroscopy.

The memoir by Dr. Carl Barus, issued as part of vol. xxix., Smithsonian Contributions to Knowledge, describes experiments with ionised air, begun by Dr. Barus some years since, and recently prosecuted under a Hodgkins grant from the Institution. The research was tributary to an investigation of the colours of cloudy condensation. Lord Rayleigh's famous theory, if applied, would stop at the deep reds of the first order, terminating in opaque, whereas in the laboratory experiments exceptionally brilliant colours, extending almost into the third order of Newton's series, may be produced. It was thus essential as a preliminary step to investigate appropriate means for the production of nuclei, to determine their number per cubic centimetre, their velocity, their association with ionisation, the effect of the pressure of an electric field, &c. This was the general trend of the experiments by Dr. Barus. The endeavour was made with the aid of the condensation tube to show that the nucleus has a specific velocity of its own, and that this is retained even in the absence of an electric field. The application of this principle to plate, to tubular, and to spherical condensers leads, in every case and in spite of the variation of method, to an order of values as to the number of particles in action, agreeing with the data obtained by other investigators from different experiments and theoretically different points of view. A second grant has been approved on behalf of Dr. Barus, and a new memoir on the structure of the nucleus, detailing experiments subsequent to those described in the volume just published, is soon to be submitted by him.

The experiments in air resistance by Mr. C. Canovetti, which were begun at Brescia, Italy, have been continued, and by means of an ingenious apparatus he has prosecuted a research which has been reported upon in detail, with illustrations accompanied by tables giving the numerical results attained.

Dr. von Lendenfeld, of the University of Prague, who has been assisted by a grant from the Hodgkins fund, reports that his studies are now sufficiently advanced to enable him to begin the preparation of his manuscript for publication. Telephotography has been extensively and successfully used in this research, and the summary of work already submitted is accompanied by interesting illustrations. A monograph embodying the results of the completed research, which will be published later, will present an anatomical and physiological study of insects, the lower vertebrates (Exocœtus, Draco, &c.), birds, mammals (Petaurus, Geleopithecus, &c.), and will treat of the polygenetic development of the organs of flight in animals. The physical properties of the air, wind velocities, resistance, &c., will be considered, and it is hoped that the publication will not only prove of general interest, but will become a valuable work of reference for students.

The research into the nature of vowels by Prof. Louis Bevier, of Rutgers College, has been reported on through a series of published articles, transmitted by the author to the Institution, which record in detail the results thus far obtained. The investigation is still in progress, the vowel series from "a" to "u" being now under analysis and discussion.

A grant has been approved on behalf of Mr. E. C. Huffaker for the construction and practical application of a device intended to produce a uniform and measured flow of air through a tube of any desired diameter. This apparatus is primarily designed for use in connection with investigations in the line of biology, and it has already been applied to exact experiments in the development of the embryo in the egg. It is hoped that by means of this invention facts may be established which will prove of practical value.

The meteorological investigations in connection with air currents at varying altitudes, heretofore reported on as conducted by Mr. A. L. Rotch at Blue Hill Meteorological Observatory, have been supplemented this year by a series of experiments on the lift and drift of the wind on plane and curved surfaces.

Dr. Morris W. Travers, of University College, London, has received a grant, and is now engaged in an investigation which will deal largely with the liquid properties of hydrogen.

National Museum.—This museum, established in the fundamental Act creating the Smithsonian Institution, grew up largely from its private collections, but it is important to consider that now it has grown into something which represents more nearly the large purpose of Congress in its foundation and that it is becoming a "National" Museum. It differs from most other museums in that its primary function was held to be not so much the entertainment or instruction of the resident population as the preservation and arrangement of the collections brought together by the Government of the United States. These collections now outnumber by some millions of specimens those which it has been possible to place upon exhibition in the present inadequate quarters. The number of specimens received during the year was about 450,000, making the total number of objects nearly five and a half millions.

Bureau of American Ethnology.—The work of this Bureau has related largely to a study of the origin, physical and mental characteristics, arts and industries, food supply, social and political institutions, religions, and languages of native American tribes.

Field work was conducted in Alaska, Arizona, California, and in several other States and Territories, as also in British Columbia, Mexico, Greenland, and in Porto Rico, while useful information and material was obtained from correspondents and special collaborators. Special attention was devoted to a study of those aboriginal industries which appeared to bear practical relations to modern life, particularly to aboriginal methods of house building and irrigation, and to food sources in those tropical and arid regions that formerly sustained a population five to ten times larger than at the present day. A noteworthy investigation of aboriginal industries was conducted in Porto Rico, and a special report of the native resources of that island is in preparation.

A special study was made of a ceremony among the Pawnee Indians embracing songs of interest in the development of music and poetry, and to early phases of the drama, the memoir being accompanied by the primitive music recorded by the aid of the graphophone, and with photographs of movements and objects introduced in the ceremony.

International Exchanges.—During the last fiscal year there was handled 125,796 packages, the packages sent abroad numbering 87,149, and those received from foreign countries 38,647. The number of parcels exchanged with Germany was 20,679, and with Great Britain 19,912. France comes next with 11,378, and then Mexico, Italy, Austria-Hungary, and Russia.

It has long seemed desirable to establish more adequate exchange relations with Japan and China, but efforts in that direction have so far been without success. In Great Britain, Germany, and Austria-Hungary, it is still necessary to employ salaried agents to carry on the work, the Governments of these countries for various reasons not yet having organised international exchange bureaus.

Five years ago, in 1897, the total number of correspondents or participants in the exchange service was 28,008, while the aggregate has now reached 38,200 addresses of libraries and individuals in 154 countries scattered all over the civilised world, even in some of the remotest corners of India, Asia, Australia, and Polynesia.

The general benefit of the service to the scientific world can hardly be measured. Largely as a result of these international exchanges there has accumulated in the Library of U.S. Congress a mass of scientific and Government publications that is probably not surpassed anywhere, and could scarcely have been secured in any other way.

National Zoological Park.—Dr. Langley has in previous years called the attention of the Regents to the want of a grant for collecting and preserving some of the great land and marine specimens of the Western territory now rapidly approaching extinction, and he again urges the immediate need of doing something, even on the smallest scale, before it is entirely too late. It is hoped that means will be provided to meet these wants by the establishment of at least

two small stations or ranches in Alaska, one in the interior, where may be secured specimens of the great moose, the great bear, and other disappearing animals of the land fauna; the other "ranch" to be on the coast for the collection of the walrus, the sea otter, the great sea lion of Steller, and other important vanishing marine species.

The animals in the National Zoological Park at the close of the fiscal year included 506 mammals, 232 birds, and 145 reptiles. The accessions of the year numbered 314. More than half of these accessions were gifts to the Government, several of the most interesting animals having been secured through the cooperation of United States consuls and other officials. A fine specimen of grizzly bear, also some antelope, deer, elk, and cinnamon bears were received from the Yellowstone National Park.

The native game, formerly everywhere plentiful, has grown so nearly inaccessible that only after years of effort have there at last been procured a single young male specimen of the great Kodiak bear and two big horn or Rocky Mountain sheep.

The Astrophysical Observatory:—The principal work of the Astrophysical Observatory during the past year has continued to be the study of the sun and its radiation. While fully acknowledging the interesting nature of astrophysical investigation of the stars and nebulæ, the study of the sun has a far superior practical importance, for were the former bodies to be wholly blotted out, they would be missed chiefly as objects of scientific interest, while with the sun would be abolished life itself. The solar researches have mainly been concerned with determining the amount and nature of the absorption of solar radiation in the earth's atmosphere and in the solar envelope. These researches are preliminary to, and form an essential part of, the measurement of the total radiation of the sun. A presumption exists, almost amounting to certainty, that the total radiation of the sun is variable in some relation to the appearance of sun-spots, but nothing is yet known to fix definitely the amount of this supposed variability or to measure its effect upon the earth, though that effect, if so fixed, cannot but be of interest to every inhabitant of the earth's surface.

The instrumental means, which thus have been the subject of incessant study and improvement here during the past ten years, for investigating such questions, are more efficient than at any previous time. The detailed report shows that automatic bolometric curves accurately representative of the amount and distribution of the solar energy at the observer's station may now be obtained in a few minutes, covering nearly the whole spectral region which reaches sea level, and where occurs much of the great and varying absorption by water vapour which influences our terrestrial temperatures so greatly.

Some twenty years ago, when Dr. Langley invented his "bolometer," the instrument was able to measure temperature to about one one-hundred-thousandth of a degree. Since then, during fifteen years of constant advance, latterly associated with a great improvement of the adjuncts, particularly of the galvanometer, at the hands of Mr. C. G. Abbot, this has been brought to measure somewhat less than one-hundred-millionth of a degree, and this almost infinitesimal amount is distinguished with readiness and precision. It is this increased precision which is associated with all the improvements in the work of the year here described.

It is the variability of the absorption of our air which now offers the greatest difficulty to the work. Dr. Langley cherishes the hope that a solar observatory will one day be established high in a clear and dry air, the chief aim of which shall be to solve the questions of the amount of radiation of the sun, the changes in this total amount, and the consequences of such changes on the earth.

The interest of this solar study is peculiar among all the subjects of astronomical research, for it is not only a scientific but a utilitarian interest of such high importance that it has among its remote possibilities the forecasting of the coming seasons and harvests, and of conditions immediately practical, from those which affect the price of the labourer's dinner up to those which, to use the weighty words of Prof. Newcomb, may bring to light not merely interesting cosmical processes, but "cosmical processes pregnant with the destiny of our race."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The General Board of Studies report that in their opinion it is expedient to reestablish the chair of surgery, which has been suspended since Sir George Humphry's death. They propose a stipend of 600*l.* a year, with freedom to undertake private practice, and the right to be *ex officio* surgeon to the hospital and to hold a college fellowship.

A special syndicate has been appointed to consider arrangements for the future conduct of the engineering department, in view of the approaching departure of Prof. Ewing. A bust of the late Dr. John Hopkinson has been presented to the Hopkinson Laboratory, and will be unveiled during the present term.

THE second reading of the London Education Bill was carried in the House of Commons on April 29 by 300 votes to 163.

AT a meeting of the Court of Governors of University College, Liverpool, held on May 2, the chairman alluded to the endowment of a chair of electrotechnics, for which special purpose a donation of 10,000*l.* had been made by Mr. Jardine, and stated that they hoped to receive other special donations in order to establish professorships of applied mechanics and applied mathematics. A new building for electrotechnics and biology is to be erected, which it is hoped will be one of the most perfect of the kind in the country. It was also announced that, assuming all went well, and that the charter constituting the Liverpool University College a separate university was granted in June or early in July, the necessary Act of Parliament would probably be passed during the present session.

THE annual conference of the presidents, deans and executive officers of many of the institutions for the higher education of women in the United States was held this year at Smith College on April 18. The association, which numbers among its members eleven colleges for women and co-educational institutions, as well as associations and individuals, maintains a table at the Zoological Station at Naples, awarding places at it to from one to five persons each year. A place at the American Women's Table at this Station for 1903–4 was awarded to Dr. Grace Emily Cooley, associate professor of botany at Wellesley College, who will thus become scholar of the association. An additional award has, however, been made this year, that of the prize of 200*l.* offered two years ago for the best piece of scientific research work done by a woman. Twelve professors representing the biological, chemical, and physiological sciences act as board of examiners for the association. This year they considered eleven scientific investigations, and awarded the prize to Dr. Florence R. Sabin, assistant in anatomy at the Johns Hopkins University Medical School, for the results of an investigation on the origin of the lymphatic system. Honourable mention was given to the paper on the life-history of Pinus by Miss Margaret Ferguson. The prize of 200*l.* is again offered, to be awarded in 1905.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 24.—Mr. T. H. Blakesley, vice-president, in the chair.—Mr. W. B. **Croft** exhibited several novel and ingenious pieces of physical apparatus.—Dimensional analysis of physical quantities and the correlation of units, by Mr. A. F. **Ravenshear**. The object of this paper is to knit together various divergent views which are current on the subject of dimensions. It is shown that while (1) dimensional analysis and the correlation of units of different kinds can be pursued in one direction until, with completed correlation, we arrive at degrees of undifferentiated quantity, a different procedure may be followed which (2) gives rise to various systems of dimensions descriptive of the physical relationships of the quantities treated. The conditions giving rise to dimensional relations are first set out, and it is proposed to distinguish the purely quantita-

tive reading of a dimensional formula by enclosing the sign of equality in square brackets thus:—

$$[\text{force}][=][M][L][T^{-2}]$$

and the reading of it as a physical identity or equivalence thus:—

$$[\text{force}]\equiv[M][L][T^{-2}].$$

The dimensional relation $M=L^3T^{-2}$ derived from the law of gravitation is examined at length. This relation, combined with the demand for the complete correlation of all dynamical units, is shown to require the adoption of the convention

$$[L][=][T][=][M].$$

This result is interpreted by (1) above. Systems of dimensions are next discussed, with the aid of illustrative tables, and it is shown that by employing different physical laws as bases many different systems may be constructed.—Mr. R. J. **Sowter** read a note on dimensions of physical quantities. Mr. Ravenshear has shown that any physical quantity is expressible in terms of the dynamical quantities L, M and T, in different ways, but that all the various ways are connected with one another by an index law. One interpretation of this is that the dynamical factors are complete in themselves. They express change-ratios, and have no qualitative significance. μ, k, γ, &c. do not contain dynamical factors, but carry with them the physical qualities or characteristics of the quantities associated with them. Any physical quantity, on this hypothesis, is expressible as $Q=N(D^n)q$, where N is a mere number, (D^n) is a dynamical factor indicating a quantitative measurement process, and q is a quality factor of the nature of Q.

Geological Society, April 8.—Mr. J. J. H. Teall, F.R.S., vice-president, in the chair.—On the probable source of some of the pebbles of the Triassic Pebble-Beds of South Devon and of the midland counties, by Mr. O. A. **Shrubsole.** The author describes the Budleigh-Salterton Pebble-Beds. The supposition is natural that Devonian rocks were once represented either in the Calvados district or in some region in the same drainage-area as that which has supplied the Ordovician element. The Grès de May of Normandy appears capable of furnishing abundant material, not only for the Ordovician pebbles of the Budleigh-Salterton Pebble-Bed, but also for a great deal more. A list of species common to the Grès de May, of May itself, and the Budleigh-Salterton deposit is given. The author is struck with the resemblance of the Midland Bunter to that of Devon. Strong family likenesses subsist between certain specimens in the northern and southern Bunter and some of the undisturbed rocks of Normandy. A list of fossils from the Midland Bunter contains three southern forms. Fourteen out of twenty of the Drift and Bunter fossils are found at Budleigh-Salterton and in Normandy.—Note on the occurrence of Keisley-Limestone Pebbles in the Red Sandstone-Rocks of Peel (Isle of Man), by Mr. E. L. **Gill.** Pebbles of a coarsely-crystalline, greyish-white, mottled limestone, collected by Prof. W. Boyd Dawkins from the conglomerates at Whitestrand, contain the following fossils:—*Illaenus Bowmanni*, var. *brevicapitatus, Primitia Maccoyi, Orthis calligramma, O. testudinaria, O. biforata, Rafinesquina deltoidea, Plectambonites quinquecostata, Atrypa expansa, Hyatella Portlockiana, Dayia pentagonalis, Platyceras verisimile, Stenopora fibrosa*, and crinoid-stems. This assemblage of fossils corresponds strikingly with that of the Keisley Limestone, and it is therefore concluded that the pebbles have been derived from that rock.

DUBLIN.

Royal Irish Academy, April 27.—Prof. Atkinson, president, in the chair.—Observations on the temperature of the subterranean organs of plants, by Dr. Henry H. **Dixon.** Previous experimenters on the temperatures of plants have confined their investigations to the aërial organs. Dutrochet alone experimented with subterranean organs, but only after removal from the soil. He believed that these organs are at the same temperature as their surroundings. From the experiments described in this paper we may infer that (1) subterranean organs, *e.g.* bulbs, like aërial organs, may have during active growth a higher temperature than their surroundings. The amount of this temperature-elevation may be as much as 0.06° C. (2) After the period of active growth is passed, this temperature-elevation is no longer noticeable. (3) There is no true indication of a *spontaneous* periodic diurnal rise in the temperature of subterranean organs, such as has been recorded by other writers for aërial organs. A periodic diurnal rise may occur owing to the periodicity of the temperature of the surroundings, which in its turn may cause an increase in the metabolic activity of the plant, and so give rise to a periodic elevation of temperature. (4) In the less massive subterranean organs the temperature rise is not sufficient to make itself appreciable above the fluctuations of the surroundings and the errors of experiment. The paper also contains an account of the errors affecting the thermo-electric method of determining plant temperatures, and also of some suggestions with a view to minimising them.

PARIS.

Academy of Sciences, April 27.—M. Albert Gaudry in the chair.—The president announced the death of M. de Bussy, member of the section of geography and navigation.—On the radiation of polonium and on the secondary radiation which it produces, by M. Henri **Becquerel.** The radiation of polonium differs from that of radium by the absence of rays resembling the kathode rays. The chief portion of the polonium rays possesses identical properties with the α-rays of radium and the canal rays of Goldstein. Up to the present these have been the only polonium rays known, but the author has recently recognised the existence of other rays, distinguished by their powers of penetration. These penetrating rays produce effects which are in every way comparable with the penetrating rays of radium filtered through a considerable thickness of metal. Hence it would appear that of the three distinct kinds of radiation possessed by radium, polonium possesses only two, the part missing being that of a kathodic nature.—The eclipse of the moon of April 11 at the Observatory of Marseilles, by M. **Stephan.**—Observation of the partial eclipse of the moon of April 11 at the Observatory of Bordeaux, by M. G. **Rayet.** The atmospheric conditions were extremely favourable for observations; one peculiarity noticed in the eclipse was that whereas in ordinary eclipses the entire disc of the moon can be seen during the greater part of the eclipse, in this case the eclipsed part of the moon had completely disappeared. This was noticed both in the eye observations and the photographs.—The catalytic decomposition of alcohols by finely divided metals, allyl and benzyl alcohols, secondary and tertiary alcohols, by MM. Paul **Sabatier** and J. B. **Senderens.** It has been shown in previous papers that metallic copper, prepared by the reduction at a low temperature, reacts with the primary alcohols, giving the aldehyde and free hydrogen. This reaction has now been extended to allyl, benzyl, isopropyl and other secondary alcohols. Allyl alcohol gives a 50 per cent. yield of propyl aldehyde, and benzyl alcohol gives hydrogen and the aldehyde. Secondary alcohols give hydrogen and the corresponding ketone in good yields, provided that the temperature does not rise too high. Tertiary alcohols split up into water and ethylene hydrocarbons. Reduced nickel gives rise to similar reactions, but there is a tendency to further decomposition, and the yields are not so good.—M. Noether was elected a correspondant in the section of geometry in the place of the late M. Fuchs.—On the observation of the eclipse of the Moon of April 11, by M. P. **Puiseux.** The extreme blackness of the eclipsed portion of the moon, noticed by other observers, was also in evidence at Paris.—The eclipse of the moon of April 11–12, by M. A. **Kannapell.** The results of observations made at the Observatory of the Faculty of Sciences at Paris.—On the deadening of the tremors of the ground. The application of a bath with a thick layer of mercury, by M. Maurice **Hamy.** A study of the theory of the use of mercury baths in preventing oscillations. An apparatus designed to carry out the conditions indicated by these researches was installed in the neighbourhood of a 4 h.p. gas engine with very satisfactory results.—The calculation of the time and height of high tide by means of harmonic constants, by M. Rollet **de l'Isle.**—Observations of the sun made at the Observatory of Lyons with the 16 cm. Brunner equatorial during the first quarter of 1903, by M. J. **Guillaume.** The observations are given in three tables showing the number of spots, their distribution in latitude, and the distribution

of the faculæ in latitude.—On certain remarkable deformations, by M. Jules **Drach.**—On the carrying of the charge in experiments on electric convection, by M. N. **Vasilesco-Karpen.** A discussion of the question of a disc, carrying a variable electric charge, and rotating about its axis, as to how far the charge is carried round by its support? A calculation is given showing the number of turns made by the charge with respect to the disc in unit time. The slipping is proportional to the thickness of the disc and to the induced electromotive force.—On the cementation of iron, by M. Georges **Charpy.** Cementation is not limited by the solubility of carbon in iron. Under certain conditions, the iron may be completely converted into carbide of iron, or the carbon may be indefinitely converted into graphite by the action of a limited quantity of iron.—On the reduction of some compounds of the halogens with metals by hydrogen; the influence of pressure, by M. A. **Jouniaux.** The reduction of the chlorides, bromides, and iodides of silver and lead with hydrogen was studied at varying temperatures, and the experimental results compared with an expression deduced from thermodynamics.—On the electrolytic reduction of potassium chlorate, by M. D. **Tommasi.**—On a reaction giving rise to symmetrical diphenyl-pyrones, by M. R. **Fosse.** The method used consists in treating the phenol orthophosphates with potassium carbonate. Details are given for the reactions with the phosphates of phenyl, cresyl, and naphthyl.—The influence of the nature of the external medium on plant acidity, by MM. E. **Charabot** and A. **Hébert.** Those salts which favour the diminution of water in the plant are precisely those for which the ratio between the volatile acids esterified and the total volatile acidity is the highest.—The influence of the radium radiation on animals in the course of growth, by M. Georges **Bohn.**—On some proteolytic ferments associated with rennet in vegetables, by M. Maurice **Javillier.**—On the production of formic acid in alcoholic fermentation, by M. Pierre **Thomas.** Yeast cultivated in a mineral liquid containing sugar, a large surface of which is exposed to the air, may give rise to considerable quantities of formic acid if nitrogen in certain forms is present. Since ammonium salts and amides exist naturally in certain musts, it is not surprising to find formic acid in the resulting wines after fermentation.

DIARY OF SOCIETIES.

THURSDAY, MAY 7.

ROYAL SOCIETY, at 4.30.—On *Lagenostoma Lomaxi*, the Seed of Lyginodendron: Dr. F. W. Oliver and Dr. D. H. Scott, F.R.S.—On the Physiological Action of the Poison of the Hydrophidæ: Dr. L. Rogers.—Preliminary Note on the Discovery of the Pigmy Elephant in Cyprus: Miss D. M. A. Bate.

ROYAL INSTITUTION, at 5.—Hydrogen: Gaseous, Liquid and Solid: Prof. Dewar, F.R.S.

RÖNTGEN SOCIETY, at 8.30.—Exhibition Evening.

CHEMICAL SOCIETY, at 8.—(1) β-Bromonitrocamphor and β-Bromocamphoryloxime. Influence of Impurities in Conditioning Dynamic Isomerism; (2) Spontaneous Decomposition of Nitrocamphor: T. M. Lowry.—The Active Constituents of *Butea frondosa*: E. G. Hill.

LINNEAN SOCIETY, at 8.—The Ingolfiellidæ, fam. nov., a New Type of Amphipoda: Dr. H. J. Hansen.—The Evolution of the Marsupials of Australia: A. Bensley.—Copepoda Calanoida from the Faröe Channel, and Other Parts of the North Atlantic: Rev. Canon Norman, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Applications of Electricity in Engineering and Shipbuilding Works: A. D. Williamson.—Electric Driving in Machine Shops: A. B. Chatwood.

FRIDAY, MAY 8.

ROYAL INSTITUTION, at 9.—Rural England: H. Rider Haggard.

ROYAL ASTRONOMICAL SOCIETY, at 5.—A Possible Cause of the Moon's Obscuration on April 11: Rev. S. J. Johnson.—*Probable papers*:—Observations of Stars Occulted by the Moon during the Eclipse of 1903 April 11: Radcliffe Observatory, Oxford.—Observations of Double Stars made with the 28-inch Refractor: Royal Observatory, Greenwich.

MALACOLOGICAL SOCIETY, at 8.—On the Necessity of Examining and Comparing the Animals before Determining some Species of the Genus Oliva: F. G. Bridgman.—Notes on some British Eulimidæ: E. R. Sykes.—Note on the Occurrence of *Planorbis marginatus*, Drap., and *Limnaea peregra*, Müll., in the Pleistocene of Bognor, Sussex: Alexander Reynell.

PHYSICAL SOCIETY, at 5.—A Spectroscope of Direct Vision and Minimum Deviation: T. H. Blakesley.—Mathematics of Bee's Cells: Prof. Everett.—The Coloured Map Problem: W. H. Price.—Note on the Construction and Attachment of Galvanometer Mirrors: Dr. W. Watson.

MONDAY, MAY 11.

SOCIETY OF ARTS, at 8.—Mechanical Road Carriages: W. Worby Beaumont.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Cilicia, Tarsus, and the Great Taurus Pass: Prof. W. M. Ramsay.

TUESDAY, MAY 12.

ROYAL INSTITUTION, at 5.—The Astronomical Influence of the Tides: Prof. G. H. Darwin, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—A Contribution to the Study of Double Monstrosities in Fishes: James F. Gemmill.—The Metamorphoses of *Ægeon fasciatus* and *Ægeon trispinosus*: Robert Gurney.—Descriptions of new Species of South American Coleoptera of the Family Chrysomelidæ: Martin Jacoby.

WEDNESDAY, MAY 13.

SOCIETY OF ARTS, at 8.—The Preservation of the Species of Big Game in Africa: E. North Buxton.

GEOLOGICAL SOCIETY, at 8.—On some Disturbances in the Chalk near Royston: Horace B. Woodward, F.R.S.—On a Section at Cowley near Cheltenham, and its Bearing on the Interpretation of the Bajocian Denudation: L. Richardson.—Description of a Species of Heterastraca from the Lower Rhætic Deposits of Gloucestershire: R. F. Tomes.

THURSDAY, MAY 14.

ROYAL SOCIETY, at 4.30.—*Probable Papers*:—The Combination of Hydrogen and Chlorine under the Influence of Light: P. V. Bevan.—On the Photo-Electric Discharge between Metallic Surfaces: Dr. W. Mansergh Varley.—The Elasmometer, a new Interferential Form of Elasticity Apparatus: A. E. Tutton, F.R.S.—On the Radiation of Helium and Mercury in a Magnetic Field: Prof. A. Gray, F.R.S., and Dr. W. Stewart; with R. A. Houston and D. B. McQuiston.—Meteorological Observations by the Use of Kites off the West Coast of Scotland, 1902: Dr. W. N. Shaw, F.R.S., and W. H. Dines.

ROYAL INSTITUTION, at 5.—Proteid-Digestion in Plants: Prof. Sidney H. Vines, F.R.S

MATHEMATICAL SOCIETY, at 5.30.—Generational Relations Defining an Abstract Simple Group of Order 32736: W. H. Bussey.—Points in the Theory of Continuous Groups: Dr. H. F. Baker.

SOCIETY OF ARTS, at 4.30.—The Province of Assam: Sir James Charles Lyall, K.C.S.I.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Applications of Electricity in Engineering and Shipbuilding Works: A. D. Williamson.—Electric Driving in Machine Shops: A. B. Chatwood.

FRIDAY, MAY 15

ROYAL INSTITUTION, at 9.—The Origin of Seed-Bearing Plants: D. H Scott, F.R.S.

EPIDEMIOLOGICAL SOCIETY, at 8.30.—The Etiology of Leprosy: Jonathan Hutchinson, F.R.S.

CONTENTS.

THURSDAY, MAY 14, 1903.

THE UNIVERSITY AND THE MODERN STATE.

III.

IN our last article on the above subject, we attempted to show the German view of the proper position of the University in a modern civilised community.

We now proceed to give, so far as a careful study of statistics can help us, a similar indication of the view held in the United States; our object being to show the real basis of the recent progress of those nations which are now outstripping us, not only in commercial enterprises, but in other ways where brain-power comes in. We are glad to know that the importance of universities as well as battleships for the maintenance of the life of a nation is at last being recognised.

Any consideration of what the nation has done for higher education in the United States must be prefaced by a reference to two laws passed in 1787 and 1862 respectively. The first Act, enacted for the government of the territory north of the Ohio, provided that not more than two complete townships[1] were to be given to each State perpetually for the purposes of a "university to be applied to the intended object by the legislature of the State." In 1862 an Act was passed giving to each State thirty thousand acres of land for each senator and representative to which the State was then entitled, for the purpose of founding "at least one college, where the leading object shall be, without excluding other scientific and practical studies, and including military tactics, to teach such branches of learning as are related to agriculture and the mechanic arts, in such manner as the legislatures of the States shall respectively prescribe, in order to promote the liberal education of the industrial classes in the several pursuits and professions of life."[2]

A reference to Table i. below, showing the number of acres of land in each of the States, the income accruing from which is available for university education, demonstrates more conclusively than any words could do how very fully advantage has been taken throughout the United States of the legislative enactments of 1787 and 1862. The table is due to Dr. Frank W. Blackmar, and is contained in "The History of Federal and State Aid to Higher Education in the United States," published in Washington in 1890.

The grant of 1862 proved insufficient, and in 1890 an Act for the "more complete endowment of the institutions called into being or endowed by the Act of 1862" was passed.

But these land grants do not exhaust the means adopted by the State to encourage higher education in the United States. In the book to which reference has been made, Dr. Blackmar summarises the principal ways in which the several States have aided higher education. They are as follows:—

(1) By granting charters with privileges.
(2) By freeing officers and students of colleges and universities from military duties.
(3) By exempting the persons and properties of the officers and students from taxation.
(4) By granting land endowments.
(5) By granting permanent money endowments by statute law.
(6) By making special appropriations from funds raised by taxation.
(7) By granting the benefits of lotteries.
(8) By special gifts of buildings and sites.

TABLE I.—*Land Grants and Reservations for Universities.*

States and Territories.	Acres.	Dates of Grant.
Ohio	69,120	1792, 1803
Indiana	46,080	1816, 1804
Illinois	46,080	1804, 1818
Missouri	46,080	1818, 1820
Alabama	46,080	1818, 1819
Mississippi	46,080	1803, 1819
Louisiana	46,080	1806, 1811, 1827
Michigan	46,080	1836
Arkansas	46,080	1836
Florida	92,160	1845
Iowa	46,080	1845
Wisconsin	92,160	1846, 1854
California ...	46,080	1853
Minnesota	82,640	1861, 1857, 187
Oregon	46,080	1859, 1861
Kansas	46,080	1861
Nevada	46,080	1866
Nebraska	46,080	1864
Colorado	46,080	1875
Washington	46,080	1854, 1864
North Dakota } South Dakota } ...	46,080	1881
Montana	46,080	1881
Arizona Territory ...	46,080	1881
Idaho Territory ...	46,080	1881
Wyoming Territory ...	46,080	1881
New Mexico Territory	46,080	1854
Utah Territory ...	46,080	1855
Total...	1,395,920	...

The result is, as Prof. Edward Delavan Perry, of Columbia University, has said,[1] "At the present time, in each of the twenty-nine of the States of the Union, there is maintained a single 'State university' supported exclusively or prevailingly from public funds, and managed under the more or less direct control of the legislature and administrative officers of the State. These States are the following:—Alabama, California, Colorado, Georgia, Illinois, Indiana, Iowa, Kansas, Louisiana, Maine, Michigan, Minnesota, Mississippi, Missouri, Nebraska, Nevada, North Carolina, North Dakota, Ohio, Oregon, South Carolina, South Dakota, Tennessee, Texas, Virginia, Washington, West Virginia, Wisconsin and Wyoming.

"The universal verdict of public opinion in the States where such institutions are maintained is that they, as State organisations supported directly by public taxation from which no taxable individual is exempt, should be open without distinction of sex, colour, or religion to all who can profit by the instruction therein given."

The figures necessary to express how much university education in the United States owes to the American Government are large, and the total amount of the aid is enormous. The following table, drawn up with the assistance of the Report of the U.S. Commissioner of Education for the year 1899–1900, will enable the reader to form some idea of the splendid resources placed at the command of American universities. The grand totals under each heading will be found in Tables v. and vi., so arranged as to show the proportion of each total available for the university education of women.

[1] In surveys of the public land of the United States, a division of territory six miles square, containing thirty-six sections.

But, as readers of NATURE are well aware, the universities and colleges of the United States have another source of income in addition to the generous provision made by the State. Every year wealthy American citizens place large sums of money at the disposal of the educational authorities for the purposes of higher education and the encouragement of scientific research. During the eleven years 1890-1901, the amount of these donations reached the grand total of nearly 23,000,000*l.*, as Table iii., compiled by Prof. Nicholas Murray Butler, shows:—

[1] Compiled by Prof. Nicholas Murray Butler, Columbia University, and published in "Special Reports on Educational Subjects," vol. xi. part ii.

From 1871–1890, the total amount of benefactions for education of the kind with which this article is concerned, was, the annual reports of the U.S. Bureau of Education show, 16,285,000*l.*, so that for the years 1871–1901, the grand total of forty millions sterling was raised by private effort for American university education.

The question naturally presents itself: What has been done by private effort in this country to assist university education during the same period? Compared with American munificence, the amounts given and bequeathed here are very small. Take in the first place the university colleges, which are largely to be regarded as a growth of the years under consideration. The financial statements contained in the "Reports from University Colleges, 1901," published by the Board of Education, reveal the fact that, including the 400,000*l.* raised for the University of Birmingham, the benefactions to the fifteen university colleges in Great Britain amounted during 1870–1900 to a little more than three millions. In the absence of systematic reports during the same period of the financial resources of the older universities of the United Kingdom, it is difficult to estimate the amount of benefactions received by them during the same thirty years. The parliamentary returns which have been published since 1898, showing the revenue of Scottish universities, suggest that their benefactions in the same time, excluding Mr. Carnegie's splendid gift, may be put at something under half a million, so that for the whole of the United Kingdom the total amount of endowment from private sources raised in these years may, without any risk of under-estimation, be said to be considerably less than five millions.

To give some idea of the result of the broad-minded policy of the legislatures of the several States and of the treatment which higher education has received at the hands of American statesmen and men of wealth, the following short summaries have been drawn up, with the assistance of the Report of the Commissioner of Education of the United States Bureau at Washington, published in 1901, for the year 1899-1900. The first (Table iv.) shows the number of colleges having endowments of certain specified amounts. The second summary (Table v.) shows the total property of all American university colleges, tabulated under the headings of fellowships and scholarships; values of libraries, apparatus, grounds and buildings; and of their productive funds. The next (Table vi.) shows the amounts of income of these colleges, and the last (Table vii.) gives the total number of professors, instructors and students in colleges of university standing.

It is interesting in this connection to compare the number of students taking university courses in this country with those in Germany and the United States. With this object in view, Table viii. has been pre-

[1] Excluding duplicates.

pared, but it should be pointed out that the number of students in our university colleges includes all above the age of sixteen, which is probably much lower than the age of the students included in the totals for other countries. It is well to remember, too, that the number of American university students is probably too high for a fair comparison with those of Germany. Many university students in the United States are really students in the higher branches of technology, and would in Germany study in technical high schools, the students of which are not included in Germany's total in the table. To make the comparisons as simple as possible the number of university students per ten thousand of population has been calculated.

TABLE VIII.—*Number of University Students per* 10,000 *of Population* (1900).

Country.	Population.	Number of Students.			Number of Students per 10,000 of Population.

United States	76,086,000	97,100			12·76

[1] Excluding Evening Students of University Colleges.

The statistics provided above make it possible to form a good estimate of the comparative amounts of importance attached to higher education in this country and in the United States. Table vi. shows that, neglecting the income accruing from the State land grants, the legislatures of individual States and the U.S. Government together supplied about 900,000*l.* for university education during 1899–1900, while the article in NATURE for March 12, 1903, shows that the total State aid to universities and colleges in the United Kingdom at present amounts only to 155,600*l.* Table vi. also brings out another important principle; it reveals the fact that during 1899–1900 private effort provided more than two and a quarter millions sterling for the colleges of the United States, and thus leads to the conclusion, which is strengthened by Table iii., that interest on the part of the State in higher education leads to a corresponding enthusiasm among men of wealth.

A comparative study of this kind is of vital national interest; our very existence as a nation depends directly upon success in that industrial warfare between the great countries of the world from which there can be no peace. The last article in this series has shown the great importance attached by German statesmen to the higher education of the directors of German industries, and how greatly superior is the provision made for this purpose in Germany to that in this country. A similar conclusion is reached by studying the subject from the American point of view; we are equally behind the United States. Unless our Government, on one hand, and our men of wealth on the other, take immediate steps, and make serious efforts to remedy these deficiencies in our higher education, British manufacturers cannot hope to hold their own successfully with either German or American competitors. The amount by which we fall short of the United States, the deficiency which must be made good simply to bring us level with America in the race for industrial supremacy, will be seen from the following deductions from the above statistics:—

(1) The amount raised during 1871–1901 by private munificence for higher education was, in the United States, more than eight times that similarly provided in the United Kingdom.

(2) In addition to the large income from State land grants, the amount provided by the State for higher education is, in the United States, six times as much as the Government grant for the same purpose in the United Kingdom, where there is nothing corresponding to the land grants.

(3) In the United States there are 170 colleges with an endowment of more than 20,000*l.*; forty-nine of these have endowments of more than 100,000*l.*, and three of more than two millions sterling. In the United Kingdom there are thirteen universities and twenty other university colleges. Four of the universities do little more than examine.

(4) In the United States nearly thirteen of every ten thousand inhabitants are studying during the day at colleges of university status; the number in the United Kingdom is less than five.

(5) The value of the endowments of institutions of higher education in the single State of New York exceeds the total amount of benefactions for similar purposes raised during thirty years in the whole of the United Kingdom. The same is nearly true in the States of Massachusetts and of California.

(6) The number of *professors and instructors* at the universities and colleges included in the list of the U.S. Commissioner of Education is 17,000. The number of *day students* in our universities and university colleges is only about 20,500, so that there are almost as many university *teachers* in the United States as there are university *students* in the United Kingdom!

In considering what should be the strength of the British Navy, the first line of national defence as it is called, it is commonly said that we must aim at making it equal to the combined fleets of any two first-class powers. When rightly regarded, the development of the brain-power of the nation is, in view of the fact that the ability to keep up the Navy depends upon commercial success, of even greater importance. Our provision of higher education, far from being equal to that of two of our chief competitors together, is by no means equal to either of them singly.

A careful study of the tables here brought together will do more than anything else to explain the success which has attended American manufactures and commerce in recent years. America has learnt that to energy and enterprise must be added trained intellect and a familiarity with recent advances in science. Other things being equal, that nation will be most successful in the competition for the markets of the world which makes the most generous provision for the higher education of its people.

We are glad that even if the Government is supine, our captains of industry are waking up; and we may conclude by a reference to the *Times* report of the speech delivered by Sir John Brunner at the remarkable gathering in connection with the Liverpool School of Tropical Medicine on Monday last, in which he repeated what he had already said to Sir Norman Lockyer in private.

"If we as a nation were now to borrow ten millions of money in order to help science by putting up buildings and endowing professors we should get the money back in the course of a generation a hundredfold. There was no better investment for a business man than the encouragement of science, and he said this knowing that every penny he possessed had come from the application of science to commerce."

GEOLOGY FOR AGRICULTURAL STUDENTS.

Agricultural Geology. By J. E. Marr. Pp. xi+318. (London: Methuen and Co., 1903.) Price 6*s*.

IN the teaching of any technical subject, like engineering or agriculture, which touches and depends upon several of the pure sciences, there has always been dispute about the amount and nature of the pure science to be exacted from the technical student, the present controversy over mathematics for engineers being a notable example. In the past, as a rule, the pure science man has ruled the roast, secure in a plausible logical position which regards the technical as "applications" of the principles laid down in the pure science, as "riders" in fact; now, however, he has, thanks to the spread of truer conceptions of education, to justify his teaching and discard those intellectual gymnastics which leave the student "as he was," and confine himself to a development of the subject to the given end.

In the book before us, Mr. Marr has put together that portion of geology with which a serious agricultural student ought to be equipped as a basis for his study of soils; more particularly the book is intended for candidates preparing for the examination for the National Diploma in Agriculture.

The earlier part of the book seems to us to be admirably suited to the agricultural student; he will get from it just the introductory knowledge of minerals and rocks, rock structures, and the work of geological agencies that he requires for an intelligent appreciation of the structure of the country. There is nothing superfluous, and, on the other hand, the proper point of view is obtained, the subject is developed as a whole, and not allowed to become a series of scraps of useful knowledge.

Two excellent chapters follow on the construction and interpretation of geological maps and sections, but we should have liked to see the later chapter on "water supply" brought into connection with this section, and treated in much more detail. To the agriculturist, structural geology is in the main important only as bearing upon water supply; it is fundamental that he should be able to read a geological map so as to gauge the probabilities of obtaining either surface or deep-seated water at a practicable depth, or to trace the origin of landsprings and decide upon a plan for tapping them or otherwise drying the land. We trust Mr. Marr will see his way in another edition to work out for the student some examples of the varying conditions of water supply, not by generalised diagrams, but from the actual survey maps.

The weakest part of the book is the last, the chapters dealing with stratigraphical geology; the economic products are but lightly touched upon, and the agricultural character of each formation is dismissed in a very sketchy and generalised fashion. If we compare the two pages or so devoted to the structure of Graptolites—the chitinous rod, the periderm, the hydrothecæ, &c.—with the amusing reference to the clay-with-flints, "Little will grow on it, though in places it has been made to yield good root crops," we see the difference between Mr. Marr the geologist, writing of what he likes and understands, and Mr. Marr "getting up" things for the agriculturist. Lastly, we should have liked a little more about the "drift" and the superficial deposits generally, for the farmer is more concerned with them than with the solid geology. In this connection we should like to know Mr. Marr's evidence for the following statement (p. 128):—

"One very important character of glacial drift from the point of view of soil formation is due to the fact that the disintegrating action of ice is purely mechanical, and, consequently, the soluble constituents of the rocks from which the drift has been derived have not been removed. These soluble constituents may be taken up by the plants but slowly, and accordingly the drift soils may not yield such abundant crops as other soils at the outset, but, on the other hand, they may continue to furnish supplies of these soluble materials long after those of other soils have been exhausted."

We are not sure we understand the meaning of this paragraph, but at any rate we demur to the apparent implication that soils become exhausted by cultivation as practised in this country.

APPLIED MECHANICS.

Elementary Applied Mechanics. By Profs. T. Alexander, C.E., and A. W. Thomson, D.Sc. Pp. xx+575; 281 illustrations. (London: Macmillan and Co., Ltd., 1903.) Price 42*s*.

THE title of this book is misleading. It is really a large and fairly advanced work dealing with certain engineering problems usually, now, classed under the headings "Strength of Materials" or "Theory of Structures." Simple problems in connection with stress and strain are taken up in chapter i., useful numerical examples being given by way of illustration and enforcement. Such examples, in fact, form a valuable feature of the work throughout. The authors—professors at Trinity College, Dublin, and Poona, India, respectively—dedicate the book to the memory of their late teacher, Prof. Rankine. Their study of that great authority has not, however, produced that terseness and lucidity of expression now so much prized. Thus the lengthening of a strut is called "augmentation," and shortening, we are led to infer, is "negative augmentation." Again, we read,

"The *Proof Load* is the stress of greatest intensity which will just produce a strain having the same ratio to itself which the strains bear constantly to the stresses producing them for all stresses of less intensity. If a stress be applied of very much greater intensity, the piece will break at once, &c."

One notices circumlocutions of this kind in various places.

Internal stresses and strains, simple and compound, are next taken up, and a picture of a model for illustrating Rankine's "ellipse of stress" is given and explained.

The stability of earthwork is dealt with in chapter iv.—as usual in such investigations, all depends on a knowledge of the "angle of repose," a very variable

quantity, and one not easily found practically. Chapter v. is devoted to the design of masonry retaining walls; the table of thicknesses for walls and the graphical solutions at the end of the chapter are particularly valuable. Chapter vi. commences an important section dealing with transverse stress, and relating mainly to the strength and stiffness of beams. After discussing the position of the neutral axis and the stress at a point in the section, the authors, oddly enough, give a chapter on the parabola, such as one might expect in a work on descriptive geometry. A clearly written chapter on graphical statics might have been introduced here with advantage. Diagrams of bending moment and shearing force are next discussed, and we come to the subject of continuous beams—one of increasing importance. Diagrams of shear and bending for girders with moving loads are then taken up at length, and a model is illustrated showing how the variations in these quantities, as a model loco. passes over a model bridge, may be exhibited to a class.

Combined live and dead loads are next considered, and approximations by the introduction of a so-called "equivalent live load" are dealt with at some length in chapter xiii., after which the *resistance* of a section to bending and shear is discussed, some neat graphical methods of finding the moment of inertia of, and the amount and distribution of shearing force at, a section being explained.

The very interesting use of the polariscope in investigating internal stress and strain, due to the late Prof. Peter Alexander, is fully described. Questions relating to curvature are next dealt with, the integral calculus being freely used. Amongst all the mass of weighty matter one does not find, so frequently as might be, useful practical rules and results set out clearly in heavy type. For instance, the point of, and amount of, the maximum deflection of a beam fixed at one end and supported at the other, with different distributions of loading, is often wanted in practice—we do not notice it prominently given here.

Struts, various kinds of trusses, linear arch ribs, &c., are taken up, analytical methods having the prominence rather than graphic methods, though the latter are employed to a very limited extent.

Tables relating to the "two-nosed catenary," the design of segmental arches, and other like matters bring this not at all elementary, yet valuable, work to a close except for an appendix, in which graphic methods are applied to a roof truss—evidently as an afterthought. R. G. B.

OUR BOOK SHELF.

The Principles of Animal Nutrition, with Special Reference to the Nutrition of Farm Animals. By Henry Prentiss Armsby, Ph.D., Director of the Pennsylvania State College Agricultural Experiment Station. Pp. vii+614. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 17*s*.

THE growth of institutions similar to that with which the classical labours of Lawes and Gilbert in this country are associated has been nowhere more marked than in the United States of America. The natural advantages of unlimited territory and virgin soil have no doubt much to do with the position of agricultural industry in that country, but added to this has been the recognition by the American people that farming, to be a success, must be conducted on scientific principles. Our Canadian cousins cannot be said to be behind their neighbours in this respect. The numerous and valuable memoirs which are being constantly issued from these agricultural experiment stations speak much for the industry and acumen of those engaged in conducting and superintending research there.

Dr. Armsby's book is a very successful attempt to present the present results of such work, so far as it relates to nutrition, in a systematic manner. It is, however, not a mere handbook for the stock raiser, but will amply repay careful perusal by students of physiology. It is a veritable mine of valuable statistics, and nowhere do we remember to have seen more clearly stated the great problems of metabolism and the methods by which they have been, and may be, solved. The law of the conservation of energy is as true for the chemistry of the living organism as it is for that of the laboratory, and it has been Rubner's epoch-making work to demonstrate that this can be experimentally verified. Much in the present book is naturally taken from Rubner; other names prominently quoted are those of Zuntz and Atwater. References are given to all important papers cited, and this materially enhances the value of Dr. Armsby's book. Where so much is excellent, it seems rather like carping criticism to point to minor deficiencies. We cannot, however, help noticing that the author's views on the digestion of proteids taken from a book published nearly ten years ago are somewhat antiquated; Kühne's theory on the hemi- and anti-products of gastric proteolysis has now been abandoned. The statement, also, that the fat of the food is absorbed largely in the form of an emulsion requires revision. In connection with the question of uric acid formation, Dr. Armsby does not appear to have grasped the now well-established fact that the formation of this substance in the bird is mainly synthetical, while in the mammal it is mainly, if not entirely, oxidative; he need not, therefore, hesitate to accept the view of its origin from nuclein and purin in these animals.

We, however, congratulate the author most sincerely on the book as a whole. So many books that one comes across nowadays are repetitions or imitations of others that it is refreshing to come across one which forms a material addition to knowledge.

Chemical Technology. Vol. iv. Electric Lighting. By A. G. Cooke, M.A., A.M.I.E.E., and Photometry, by W. J. Dibdin, F.I.C., F.C.S. Pp. xviii+378. (London: J. and A. Churchill, 1903.) Price 20*s*.

ONE must not expect too much of a book which aims at treating, in less than 300 pages, the whole subject of electric lighting, from the generation of electric energy in the central station to the manufacture of the lamp for its consumption in the user's house. As a work of reference for technical men engaged in other branches of work, but coming occasionally into contact with electrical engineering, this book should prove useful, just as an article in an encyclopædia is useful. And just in the same way as an encyclopædia article is defective, it seems to us that the book before us fails; by endeavouring to give too much information it only succeeds in giving too little. These objections apply rather to the scheme of the work than to the way in which Mr. Cooke has carried it out, which is as satisfactory as possible in the circumstances. In some instances the book is very much up-to-date; thus, it is probably one of the first text-books containing a good description of the Nernst lamp, though it is to be

regretted that the type of lamp illustrated is not the one sold in this country. In other places there is an apparent want of knowledge of recent progress, as, for example, where the oscillograph is spoken of as an instrument of little value, the point-to-point method being described as more practical. These, however, are minor blemishes, such as must be expected in a comprehensive work in which different branches are not written by separate experts. On the whole the book is to be commended; the illustrations and curves are good and well selected.

The last hundred pages of the volume deal with the subject of photometry; all the more important types of photometer are described and illustrated, and the various standards of light are carefully considered. It is perhaps to be regretted that this part of the book should refer more especially to gas photometry, since the remainder is devoted to electric lighting; but then it is altogether somewhat surprising to find a book on electric lighting forming one volume of a series on chemical technology. M. S.

Die empiristische Geschichtsauffassung David Humes, mit Berücksichtigung moderner methodologischer und erkenntnistheoretischer Probleme. Eine philosophische Studie von Dr. Julius Goldstein. Pp. 57. (Leipzig: Verlag der Durr'schen Buchhandlung, 1903.) Price 1.60 marks.

THIS essay may be described as a chapter in the history of applied philosophy. In Hume the author sees an unique example of the philosopher applying his own principles to history. In this case the experiment was of little advantage to history. Hume's well-known views on causation, the self, and uniformity leave history destitute of any "inner essence," individuals or real meaning.

The author relieves these somewhat trite observations by concrete examples from Hume's "History of England." Apart from these, the essay has been, in the main, anticipated by Leslie Stephen's "English Thought in the XVIIIth Century." Perhaps we should not forget that this is a German book. Its value lies solely in focusing attention on Hume as an example of the way history should not be written. The real value of Hume's work is hardly touched; he is ranked above Voltaire, but shares with the Enlightenment the glory of having failed well. As to the question of method, there is here only a negative contribution. Not only has the failure of Hume and the Enlightenment left chaos, but the author leaves it quite an open question how history is to become a science. That may be wisdom, but then the title seems disproportionate. In the references to Green and Grose for P.H. (*passim*) read T.H. On p. 51 (note) the reference is i. S. 378, &c. (not ii.). Siegwart is, of course, Sigwart (p. 11). "Aepinus" (p. 39) and the Englishman "Marivaud" (p. 56) are scarcely recognisable, but probably symbolise "Aquinas" and "Merivale."

G. S. B.

Arithmetic. Part i. By H. G. Willis, M.A. Pp. viii+256+l. (London: Rivingtons, 1903.) Price 1s. 4*d*.

THIS collection of examples on the simpler parts of arithmetic is arranged in a convenient and workable manner. The exercises are divided into thirty-nine groups, each containing work enough for two or three lessons; there are, moreover, duplicate sets of exercises which can, if necessary, be used in alternate terms. Oral questions are set at the beginning of each exercise. A few examination papers, tables of reference, and answers are given at the end of the book. The volume is likely to prove useful for junior forms.

LETTERS TO THE EDITOR.

Action of Live Things in Mechanics.

DR. HOBSON (p. 611) appears to hold the view that if dynamical laws are exact and irrefutable, the universe must be a completely determined mechanical system, with only one, and that a necessary, solution.

I hold, on the other hand, that though dynamical laws when properly stated are perfectly true, they do not cover the whole region of existence, and that, accordingly, it is possible for live things to affect the motions of matter in an unpredictable and capricious manner, though always in accordance with the laws of motion.

Dr. Hobson says, or implies, that they cannot so interfere without destroying the complete validity or supremacy of mechanical laws, and that they may as well upset the law of the conservation of energy as any other.

I reply that it is a question of fact whether they do or not. Experience seems to me to prove:—

(*a*) That live animals do introduce fresh considerations and do disturb things—do not take the path of least resistance, for instance; they are actuated by all sorts of non-mechanical motives, climbing the Matterhorn when there is no necessity, and building structures which would not otherwise be built.

(*b*) That in so doing they never run counter either to the conservation of energy or to any other fundamental mechanical law; they utilise the mechanical energies which lie ready to their hands, directing them, but leaving their amount unaltered.

[I emphasise the energy aspect because I so often find philosophers assume that any interference of life with inanimate matter must contradict the conservation of energy, or else must involve the doctrine that life itself is a form of energy.]

I ask Dr. Hobson to admit that a unique solution of all future material motions is only possible in a problem from which all other aspects of the universe have been abstracted, so that we limit ourselves by hypothesis to a purely dynamical system.

There are many things in the universe beside mechanics, some of which, by odd chance, are enumerated in a footnote accidentally occurring below Dr. Hobson's letter. For simplicity it is customary to eliminate all these from dynamical problems. But the questions at issue are:—

(1) Whether any of these things can interact with or influence a dynamical system at all.

(2) Whether they can so interact without upsetting or contradicting any fundamental dynamical laws.

I wish to answer both these questions in the affirmative. But it must be understood that by "dynamical laws" I mean the fundamental ones—let us say those of Newton. I do not mean modern generalisations or comprehensive summaries, like the principle of Least Action, the applicability of which can only be postulated on certain simplifying assumptions—assumptions or abstractions which, in the present instance, merely beg the question in dispute.

If Dr. Hobson does not agree with this, I trust he will give us the benefit of his further criticism.

May 2. OLIVER LODGE.

The Glorification of Energy.

PROF. TAIT, whenever he wrote of the principle of the conservation of energy, almost invariably spoke of it as the "grand" principle of conservation of energy; and, following his lead, all but the most sober mathematicians use the laudatory adjective when they write about this particular physical principle.

It may not be altogether superfluous to point out that there are other principles equally entitled to the epithet "grand." For example, there is the "grand" principle of the conservation of matter; there is the "grand" principle of the conservation of force, the sum total (algebraic) of which in the universe is zero, according to Newton's

Axiom ii.; there is the "grand" principle of the conservation of momentum, the algebraic sum total of it along any direction in the universe being constant (and possibly zero) by Newton's Axiom iii.; as well as the "grand" principle of the conservation of energy.

Now I hold that it is invidious to apply laudatory epithets of various degrees to these principles; but it may not be wrong to point out that in many respects the momentum principle has a marked advantage over the energy principle, the former being very often very easily, and without any danger of error, applicable, while the latter (owing to the elusiveness of energy) is full of danger to the unwary.

Postulating now the existence of spirit, we find a difficulty in defining this entity; but no greater mystery attaches to it than that involved in matter. The spiritualists imagine that they gain something by calling matter hard and contemptuous names—"mere" matter, "gross" matter, "mere gross" matter, &c. The names are harmless, and do not assist ideas in any way.

Postulating, then, the existence of a spiritual domain, the crucial question arises: does Newton's Axiom iii. hold for the interaction of the domains of matter and spirit? If it does, there is no dynamical principle interfered with; *in the dual domain* there are conservations of force, of momentum and of energy; but in the physical universe, *taken separately*, neither force nor momentum would be conserved, although energy might. On the other hand, if Newton's Axiom iii. does not hold for the interaction of the two domains, no principle of conservation could be enunciated for either domain, or for the system of the two together.

Sir Oliver Lodge is anxious to make out the existence of a spiritual domain, and to allow it a certain influence on the physical, which influence, however, "perturbs physical and mechanical laws no whit." How does he effect this? By assuming (to put the thing into mathematical language) that the forces exerted on material things by the spiritual are forces which do no work—such as are reactions of smooth fixed surfaces, tensions of inextensible cords, &c. These are sometimes called "deviating" forces. Sir Oliver calls them "guiding and controlling" forces. But it matters not what they are called, they fail in their object. They allow, indeed, the physical universe to keep its sum total of energy intact, but they infallibly alter its total momentum and total force in every direction.

When Sir Oliver says "guidance and control are not forms of energy, and their superposition upon the scheme of physics perturbs physical and mechanical laws no whit," he says what is perfectly true of any conceivable forces—whether merely "guiding" or not. However force may be produced on a material particle, the effect on the particle will certainly be in accordance with Newton's Axiom ii.; so that, in the sense in which Sir Oliver's statement is true, there is no necessity to postulate that spiritual forces are forces which act on matter but do no work.

It is a physical and mechanical law that when any system of material particles is subject to no forces but its own internal forces, the centre of mass of the system is either at rest or in uniform motion in a right line, and also that its sum total of energy, kinetic and dynamic, is constant. But if Sir Oliver Lodge implies that *both* of these results can remain unaltered if that material system is acted on by spiritual forces, he is certainly wrong. His deviating, or "guiding," spiritual forces can leave the total energy (kinetic and dynamic) of that material system unaltered, but they must inevitably interfere with the rest, or constant motion, of the centre of mass. Many of his readers may take this meaning out of his words; but I am sure that he cannot intend to be thus understood.

It seems to me that Dr. Hobson in his letter on the subject has done well to direct attention to the real status of the "grand" principle of the conservation of energy.

GEORGE M. MINCHIN.

Coopers Hill, Englefield Green, Surrey.

Psychophysical Interaction.

As a psychologist I have read with deep interest Sir Oliver Lodge's paper in your issue of April 23, and I write to ask him to make clear some points which his paper leaves obscure to my mind. Those of us who are not mathematicians feel themselves to be very much at the mercy of those who are, and we can only beg the physicists to remember our infirmity and to put their statements before us in the clearest, simplest, and most carefully chosen language. Sir Oliver Lodge, as Clerk Maxwell did before him, throws out to psychologists the suggestion that mind may act upon body by exerting guidance without doing work. Such guidance, we are told, may be effected by the application of force to moving masses in the nervous system in directions perpendicular to the direction of the movements of those masses. "Guidance is a passive exertion of force without doing work; as a quiescent rail can guide a train to its destination, provided an active engine propels it." This is the sentence that I find so indigestible. And my confusion is but increased by Sir Oliver Lodge's further illustrations. He distinguishes two kinds of force. "Force in motion is a 'power,' it does work and transfers energy from one body to another. But a force at rest—a mere statical stress, like that exerted by a pillar or a watershed—does no work, and alters no energy; yet the one sustains a roof which would otherwise fall, thereby screening a portion of ground from vegetation; while the other deflects a rain-drop into the Danube or the Rhine." And, again, we read that life can exert "the same kind of force which can constrain a stone to revolve in a circle instead of in a straight line; a force like that of a groove or slot or channel or 'guide.'" My first question is, Is it fair to say that the pillar supporting the roof exerts a force in the same sense as the rail which guides the train, the roof which guides the rain-drop, or the hand which holds the string? In the first case there is no motion, and therefore no change of direction of motion, no alteration of energy; in the other cases there is motion and alteration of direction of motion. Secondly, is it fair to call the rail quiescent? In guiding the train round a curve does not the rail, and the mass to which it is made fast, suffer an acceleration or a change of motion in the direction opposite to that of the train? When I swing round a heavy ball on a string, and feel it pulling my hand centrifugally, and when by muscular effort I resist the pull, is that "a passive exertion of force without doing work"? Or, if the string is fastened to the end of an upright pole, is there not movement of the mass to which the pole is fixed in the direction opposite to the deflection of the movement of the ball? Every kind of mechanical guidance that I can picture to myself seems to imply action and reaction, change of direction of one momentum seems to imply always an opposite change of direction of an equivalent momentum. This is, I suppose, the mechanical law of conservation of momentum, of which Prof. James Ward tells us that it is incompatible with the conception of guidance without work. I ask Sir Oliver Lodge whether we are to understand that he is prepared to throw this one mechanical law to the wolves in order to preserve the rest of the creed of the physicists unharmed by Prof. Ward's attack? Or are we to understand that he repudiates the law of conservation of momentum *in toto*? In that case, I ask him to describe for us clearly a single case of mechanical guidance in which momentum is not conserved, or, since my use of the phrase may be technically incorrect, I ask him to describe a case of change of direction of motion of any mass produced without expenditure of energy or opposite change of direction of motion of other mass or masses.

I submit that Sir Oliver Lodge abstracts from the idea of motion the attribute of direction in space, and that such abstraction is illegitimate, save for certain purely theoretical purposes. All motion has direction in space, which would seem to be an essential element in all considerations of energy values. Sir Oliver tells us that life and mind cannot generate energy, though they can guide moving masses by exerting forces perpendicular to the direction of motion. But consider, then, the following case. Imagine a universe consisting of two inert masses flying through empty space in the same direction and at the same rate, and a soul contemplating them. That universe would be devoid of energy. Then suppose the soul to exert a force upon one of the two masses, perpendicularly to its direction of motion, so as to swing it round through a semicircle until it rushes to meet the other mass. The soul, by "guidance," has then created energy, and I take it that the same considerations would hold true in our more complex universe.

But this difficulty in conceiving that mind or soul can play a part in the world of matter by acting upon masses in the brain exists only for those who persist in holding the untenable hypothesis that all energy is kinetic energy, is the motion of matter. This has proved, of course, an excellent working hypothesis, but that it is true of all forms of energy is nothing more than a pious hope. Yet it is the definition of energy in these terms (tacitly or explicitly) that perpetuates the ancient difficulty of conceiving the relations of mind and body, and it is the persistent adherence to this conception that, on the one hand, has landed so many minds in the absurdities of psychophysical parallelism, and, on the other hand, drives so many others to refuse a general acceptance of the law of conservation of energy, and to believe in an activity of the soul unconditioned by the past, a belief which destroys the rational basis of morals and renders a science of history and of society impossible.

To me it seems that this fundamental problem can only be properly stated when we cease to regard matter as the ultimate physical reality, when with Prof. W. Ostwald we say, "Matter is no longer present for us as a primary conception; it arises as a secondary phenomenon through the constant coexistence of certain forms of energy. We shall therefore have to frame the question in a new form—How are psychical phenomena related to the energy-concept?" and "that in the case of psychical processes we have to do with the rise and the transformation of a special kind of energy, which we, in order to be able to speak of it, will name provisionally psychical energy (geistige Energie)."[1]

Haslemere, April 26. W. McDOUGALL.

I HAVE pleasure in answering Mr. McDougall's questions so far as they are addressed to me.

In the first place I have not presumed to say how psychic control actually is exercised; but, in contradistinction to those who hold that control or guidance is impossible without the generation or introduction of fresh energy, I have pointed out that very simple and familiar mechanical arrangements do constantly exert guidance without doing any work; for instance, a line of rails.

Mr. McDougall thereupon asks me whether the line of rails is really quiescent, whether it is not subjected to an opposite acceleration. I reply yes, but what of that? The yield of rail is infinitesimal, but whatever its magnitude it is such as to make the guidance less effective, not more; it is a passive yield to pressure, not an active exertion of energetic work-performing force in the direction of motion or of change of motion. The recoil of a gun is of no assistance in propelling a bullet.

In so far as the rails yield to the train as it enters Euston by a curve, they guide it not to Euston as it was, but to a slightly shifted destination. No matter, they guide it, and they have had no energetic or propelling power whatever.

He asks me further if I fully admit the principle of universal equal opposite reaction, and the consequent conservation of momentum.

Certainly I do; but I do not admit the (as I think) mistaken use Prof. James Ward makes of the principle in the sentence which he refers to.

Mr. McDougall seems to overlook the fact that kinetic energy is independent of direction. Whether a thing be moving north or south or east or west its energy depends on mass and speed alone. To change the speed, work is necessary; no work is needed to alter the direction. Perhaps it may be a help to him, though it is not really important in this connection, if I say that great momentum does not necessarily imply great energy. The momentum of a recoiling gun or earth is equal to that of the projectile, but the energy of the projectile is enormous in comparison with the energy of recoil.

He asks me for an example of "a change of direction of motion of any mass produced without expenditure of energy or opposite change of direction of motion of other mass or masses." But the two things are not the same. An instance of change of direction of motion without expenditure of energy is afforded by the instances we have already taken, or by any perfectly elastic rebound—that of a comet from the sun, for instance. Undoubtedly the sun thereby acquires an equal opposite momentum; but what of that? The modicum of energy in this momentum is infinitesimal, for one thing, and for another it comes from the comet, not from the sun; it renders the rebound less efficient, not more; it is no supply of energy from the central practically stationary mass. The same thing is true of a ball whirling on a string round a pole. When a boy holds the string in an active hand, it is quite easy and usual to do a little work by moving the hand a quadrant in advance of the ball, and thus to maintain, or even increase, its energy; but the force so exerted by a hand is not purely radial, it has a tangential component, and this part of it is effectively propulsive. An energetic, not a passive, centre is needed for that.

[1] "Vorlesungen über Naturphilosophie" (Leipzig, 1902).

Coming to another part of his letter; his illustration of a great display of available energy being brought about by the reversal of motion of one of two similarly flying bodies, suffers from the confusion of energy with available energy. The flying of air molecules, for instance, is in every direction, sometimes so as to be able to collide, sometimes not, but their energy is quite independent of these directional circumstances. As Dr. Hobson truly says in your issue of April 30, "the principle of energy, if applied to even the simplest dynamical system which is possessed of more than one degree of freedom, is, taken by itself, wholly insufficient for the determination of the motion of such system." That is one part of my contention, technically stated. In so far as a question of absolute velocity seems involved in the energy of a single isolated flying mass, I might refer to a discussion of that aspect of the matter in the *Philosophical Magazine* for October, 1898.

In conclusion, I perceive that Mr. McDougall, like some other philosophers, hopes to jump the admitted difficulties of psychophysical interaction by ignoring "matter" altogether and taking refuge in "energy" alone. I venture to predict that those who attempt this will find that though they may wander in dimness for a time, and may cultivate an unawareness of difficulties by failing to see them distinctly, they will not derive any ultimate satisfaction from the blindfolding; nor do I think that they will be well advised to transplant the definite physical term "energy," even though prefixed by a special adjective such as *geistige*, in order to denominate what is probably a perfectly distinct psychical entity with laws of its own. OLIVER LODGE.

THOSE of your readers who have been interested by Sir Oliver Lodge's article printed in NATURE, April 23, on the "Interaction Between the Mental and Material Aspects of Things," may be glad to be referred to Thomas Solly's essay on the Will, published in 1856.

The suggestion of Solly is that every act of the will is simply a guidance of *mental* activity, infinitesimal, indeed, in its amount in each individual act, but such as to influence, not the external world, but the character of the individual exercising it, so that the same external stimulus operates after each successive act of the will on an individual whose character has been changed by that act, whence same stimulus is no longer necessarily the same motive. By thus regarding each act of the will as a "self-determination of the subject," the acts of choice or guidance are assumed to take place in a region of activity about which we have no physical information whatever, and the interactions of material things are left absolutely untouched.

The significance of the suggestion is made extremely clear in Solly's chapter on "Liberty, a Self-Determination of the Subject," and in subsequent chapters, by means of very happily chosen geometrical illustrations.

Mohuns, Tavistock, April 26. A. M. WORTHINGTON.

Mendel's Principles of Heredity in Mice.

THE issues raised in the case of these mice are as yet of such a simple and familiar kind that the source of Prof. Weldon's difficulty is not easy to surmise. When a gamete G bearing albino and pink-eye meets a gamete G′ bearing coloured coat (in this case fawn) and pink-eye, a heterozygote GG′ was produced, with dark eyes and coloured coat. Such hybrids, as the experiments proved, gave off equal

numbers of gametes G, bearing albino with pink-eye, and G′ bearing colour with pink-eye. Consequently from GG′×GG′ we expect and obtain GG+2GG′+G′G′; and from GG′×G equal numbers (approximately) of GG and GG′. So far, GG are pink-eyed albinos; GG′ are dark-eyed with *some* colour in coat; G′G′ are pink-eyed, but with *some* colour in coat.

If we do not consider what *particular* colour GG′ and G′G′ will have, we may treat all gametes G′ as identical. But after crossing with albino such a condition would be unusual. The colour brought in by the original G′ is generally in part resolved, and various sorts of G′ gametes are formed, viz. *a*G′, *b*G′, *c*G′, *abc*G′, &c. Therefore when the hybrids breed together there will be GG′ zygotes of several colours, viz. G.*a*G′, G.*b*G′, G.*c*G′, &c.; also G′G′ zygotes of several colours, viz. *a*G′.*a*G′, *a*G′.*b*G′, &c. Each combination will have its appropriate colour and frequency, though (if the regularity be maintained) all GG′ will have dark eyes and *some* colour, and all G′G′ pink eyes and *some* colour. But as the hybrid produces G gametes equal in number to the various G′ gametes collectively, GG′×GG′ will give on an average one albino in four offspring (experiment gave nine in thirty-seven); and there is no question of one in nine. We are only concerned with *one* hypothesis (that I have set forth in "Mendel's Principles of Heredity," p. 29), and with this hypothesis the published facts are in admirable agreement.

Heterogeneous offspring from crossing two seemingly pure races may seem to Prof. Weldon an "amazing" phenomenon, but it is one with which the breeder early becomes familiar. Even albinos need not be pure or their gametes homogeneous in characters other than albinism.

Grantchester, Cambridge, May 1. W. BATESON.

MR. BATESON reconciles his statements in NATURE of March 19 and April 23 by explaining that in his first letter, when he describes certain mice as of constitution G′G′, he is deliberately denoting a whole series of different gametes by the same name.

The suggested heterogeneity among the gametes of pure albinos is now said to affect characters other than albinism, and is therefore wholly irrelevant. The avowed vagueness in the use of the symbol G′ makes it uncertain whether the fawn-and-white mice are now supposed to produce gametes of different character (with regard to coat-colour and eye-colour) or not. If the gametes of all the fawn-and-white mice used are similar, then all hybrids between these and albino mice are of similar constitution, and the fact that some are yellow, some grey, and some black is left unaccounted for. If the fawn-and-white mice produce even three kinds of gametes, G'_1, G'_2 and G'_3, then on crossing with albinos the hybrids GG'_1, GG'_2 and GG'_3 may be of different coat-colour; but since the fawn-and-white mice always breed true to colour when paired *inter se*, it surely follows that the combinations $G'_1G'_1$, $G'_1G'_2$, $G'_2G'_3$, &c., which arise from such unions (some homozygotes and some heterozygotes) give rise to mice of similar colour. It is this consequence of heterogeneity in a pure-breeding race which seems to me amazing.

In assuming that coat-colour is resolved into simpler elements when hybrids form their gametes, Mr. Bateson follows Mendel; but in such cases Mendel assumes that all the various kinds of gametes, produced by the hybrid, occur with equal frequency, and Mr. Bateson has elsewhere attempted to bring this assumption into relation with the phenomena of cell-division ("Mendel's Principles of Heredity," p. 30). In trying to fit Mr. Darbishire's facts by a Mendelian formula, Mr. Bateson abandons this hypothesis; he now says that a hybrid mouse produces (1) a series of different kinds of colour-bearing gametes, and (2) a number of gametes bearing the characters white coat and pink eye, *equal to the sum of all the other kinds of gametes together*. This departure from Mendel's hypothesis is masked in Mr. Bateson's first letter by the simple device of calling the whole series of different colour-bearing gametes by the same name G′.

Mendel's own view of the way in which compound characters behave gives a maximum possibility of one pure recessive albino among sixteen offspring of hybrids; a non-Mendelian view, lately put forward by Mr. Bateson in another case of colour-resolution (*Proc.* Camb. Phil. Soc., vol. xii. p. 52), gives a maximum of one in *nine*; the view he now suggests for mice gives one in *four*. By modifying first one and then another of Mendel's statements, his name is made to shelter almost any hypothesis, and almost any experimental test is evaded.

In the next number of *Biometrika* Mr. Darbishire will publish a series of new results, which have an important bearing on the application of Mendel's "principles" to his mice. Until these new facts are available, I do not think further discussion will be profitable, and therefore I do not propose to continue this correspondence.

Oxford, May 6. W. F. R. WELDON.

[This correspondence must now cease.—ED.]

INTERNATIONAL METEOROLOGICAL COMMITTEE.

THE International Meteorological Committee appointed by the Paris Congress of 1896 in succession to those appointed by previous congresses, commencing with the Vienna Congress of 1873, will meet this year at Southport during the session of the British Association, September 9 to 16. The committee held a single meeting in the room at the top of the Eiffel Tower in 1900; its last normal session was at St. Petersburg in 1899. It has not met in England for twenty-six years. The original "permanent" committee was appointed by the Vienna Congress in 1873, and consisted of six members under the presidency of Buys Ballot; its successor now numbers seventeen members, representing a large number of the official meteorological organisations of the world. Prof. Mascart, of the Bureau Central Météorologique of France, is president, and Prof. H. H. Hildebrandsson, of the Royal Observatory of Upsala, is secretary, having been elected to that office on the resignation of Mr. Scott, who was secretary from 1874 (the Utrecht meeting) until the close of 1899. The other members are Prof. von Bezold (German Empire), Prof. Billwiller (Switzerland), Captain Chaves (Azores, Portugal), W. Davis (Argentine), Sir J. Eliot, K.C.I.E. (India), Prof. S. Hepites (Roumania), Prof. H. Mohn (Norway), Prof. Willis L. Moore (United States), Prof. L. Palazzo (Italy), Prof. Paulsen (Denmark), Prof. J. M. Pernter (Austria), Mr. H. C. Russell, C.M.G. (Australia), General Rykatcheff (Russia), Mr. W. N. Shaw (Great Britain), and Prof. H. Snellen (Holland).

The functions of the committee are to discuss meteorological questions of international interest and formulate proposals for international cooperation in connection therewith. The deliberations have an official character in virtue of the committee being appointed by a congress of representatives delegated in response to an official invitation of one or other of the European Governments, but the committee has no executive authority. It has been the practice for the committee to appoint from time to time various "commissions" or subcommittees to prepare reports upon questions that require preliminary discussion. The members of these subcommittees are not necessarily members of the international committee. They meet from time to time on the invitation of their respective chairmen, and opportunity is often taken of the occasion of the meeting of a subcommittee to obtain more general discussion by inviting other persons interested in the special subjects to take part in the proceedings, and sometimes to become members of the subcommittee. There are at present five subcommittees, constituted as follows:—

(1) *Terrestrial Magnetism.*—Sir Arthur Rücker (chairman), Messrs. Litznar, Moureaux, Palazzo, Paulsen, von Rijkevorsel and Rykatcheff.

(2) *Radiation and Insolation.*—Prof Viollo (chairman), MM. Angstrom, Chistoni, Chwolson, Snellen, Stupart, and Tacchini.

(3) *International Weather Telegraphy.*—Prof. J. M. Pernter (chairman), Messrs. Billwiller, Mohn, von Neumayer, Rykatcheff, Snellen, Tacchini.

(4) *Cloud Observations.*—Prof. H. H. Hildebrandsson (chairman), Messrs. Mohn, Riggenbach, Rotch, Rykatcheff, Sprung, and Teisserenc de Bort.

(5) *Aëronautics.*—Prof. H. Hergesell (chairman), MM. Assmann, Erk, de Fonvielle, Hermite, Jaubert, Pomortzeff, and Rotch.

To the last mentioned the following names have been provisionally added by cooptation:—Messrs. Berson, Angot, Bouquet de la Grye, Cailletet, Rowanko, in 1898; Prince Roland Bonaparte, Tacchini, Teisserenc de Bort, Hildebrandsson, Pernter, Hinterstoisser, Moedebech de Sigsfeld, in 1900, and others in 1902.

The subcommittee on terrestrial magnetism held a very successful meeting at Bristol during the session of the British Association in 1898. All the subcommittees met in Paris in 1900, and the aëronautical committee met in Berlin in 1902. The subcommittee on cloud observations has completed its work for the time being, and Prof. Hildebrandsson's report has just been published.

The subcommittee upon weather telegraphy will meet at Southport, but information as to proposed meetings of other subcommittees is not yet forthcoming.

Two conspicuous considerations point to the forthcoming meeting of the committee as one of exceptional interest and importance. The first is meteorological. The situation of the British Isles with regard to the Atlantic must necessarily attract the attention of all meteorologists. The problems which that situation brings into prominence are doubtless among the most difficult, but at the same time the most interesting of meteorological inquiries. The second is economical or social. This country is a great centre for communication with all parts of the globe, and in spite of, or perhaps because of, its insular position, is easy of access from all quarters. There are, therefore, good grounds for expecting that the hospitality of the British Association and of Southport will result in a meeting of unusual interest as regards meteorology and the kindred sciences.

No programme of proceedings has yet been issued. The executive meetings of the committee must necessarily be exclusive, but opportunity will be afforded for the discussion of meteorological questions of general interest in connection with the meetings of Section A, as was the case with the magnetic subcommittee at Bristol. Among the new subjects which will come before the committee may be mentioned the special question of the relation between meteorology and solar physics, the discussion of which it is hoped may be initiated by the president of the British Association.

Southport has special appropriateness for such a meeting. Its meteorological establishment, the Fernley Observatory, under the direction of Mr. J. Baxendell, is a conspicuously successful example of municipal enterprise in that direction. In connection with the meeting, provisional arrangements have been made for an exhibition of novel meteorological appliances and other objects of meteorological interest. A committee representing the Meteorological Council, the Royal Meteorological Society, and the Scottish Meteorological Society, with some additional members, has been formed to carry out the arrangements.

MAORI ART.[1]

NOT only students of Maori ethnography, but those who are interested in artistic technology, will heartily congratulate Mr. A. Hamilton on the completion of his great work on "Maori Art." Although this magnificently illustrated monograph nominally deals with decorative art, it is by no means confined to that subject, as for many years Mr. Hamilton has been diligently collecting facts and illustrations which bear on the social life of the Maories. Many interesting customs have been omitted as being beyond the scope of the work; usually only those matters are considered which are connected more or less closely with objects which are capable of being figured. Not too soon has Mr. Hamilton applied himself to his labour of love; constantly throughout the book do we find uncertainty as to the exact significance of patterns and designs, and occasionally objects are figured of which the use or meaning is very doubtful. Nor is this indefiniteness due to lack of energy on the part of the author; it is merely another example of the great change that is so rapidly modifying the majority of backward peoples. "How much interesting information," Mr. Hamilton writes, "has been lost can be estimated by the fragments which have been gathered. The system of laws for the government of the body politic known as *tapu*, was the outcome of centuries of experience of practical socialism. However irregular, capricious, and burdensome it may now appear to have been, it was certainly the source of order to them, and was of great use to conserve them as a race, and to sharpen their intellectual and moral faculties, besides retaining the canon of art in its native purity. As Mr. Colenso points out, when all this was swept away, together with polygamy and slavery, without anything to replace them, the nation, as a people, was broken up. 'However distasteful,' he says, 'these three things might be to an European and Christian, they were the life of the New Zealander. They were, perhaps, the three rotten hoops round the old cask, but they kept the cask together.'"

The work consists of five parts, of which the first part contains an account of Maori canoes, with ten plates. Part ii. deals with Maori habitations, with diagrams of the construction of a house, plans and sections of a fortified *pas*, with fifteen plates, and a valuable essay by the Rev. Herbert Williams on Maori rafter patterns, illustrated by twenty-nine coloured examples; these have never been described, and therefore the explanation of Mr. Williams of the patterns is doubly welcome. The weapons and tools are described in the third part, and are illustrated by eleven plates. The fourth part deals with dress and personal ornaments, with fifteen plates. The final part is devoted to the social institutions of the Maori people, with descriptions of their games, amusements, and musical instruments, with thirteen plates. Each of the sixty-four plates contains illustrations of several objects, and there are numerous figures in the text, so that the total number of illustrations is very large, and all of them are of excellent quality and constitute a mass of information for the ethnographer, and a wealth of material for the student of art. A noticeable feature of each part is the list of words relating to the subject-matter of that part, which forms a valuable subject vocabulary, which will prove of great use to students.

The wood-carving of the Maories is very characteristic, as regards both technique and *motive*. The designs are carved with great boldness, considerable relief is employed, and the background is usually filled up with labyrinthine designs, the spaces of which are

[1] "Maori Art." By A. Hamilton. Pp. 439; 64 plates and numerous illustrations in the text. (New Zealand Institute, Wellington, N.Z Price 4*l*. 4*s*.

frequently perforated. The most common form of surface decoration consists of ridged parallel lines enclosing narrow bands or areas, which are filled up with short cross-ridges, as in Fig. 1, less frequently notched ornamentation, called *taratara o kai.*

The carvings most frequently represent grotesque human figures, often associated with a problematical creature called *manaia* (Fig. 2). Concerning the *manaia*, Mr. Hamilton says:

"On the slab are carved representations of a human figure attended by the monstrous bird or snake-headed figures so frequent in all carvings from the northern portion of New Zealand. At present no explanation is forthcoming of the esoteric meaning of these mystic

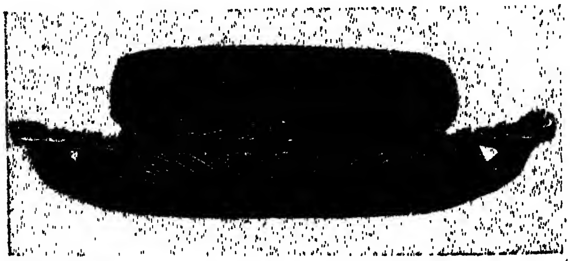

FIG. 1.—*Waka*, or box for holding greenstone ornaments or feathers for the hair.

figures. To advance a theory on the subject without ascertained facts from the *tohungas* (priests) of old would only add to the difficulties of the interpretation. Earle says, 'One of their favourite subjects is a lizard taking hold of a man's head, their tradition being that this was the origin of man.' Possibly these *manaias* may have been considered as representations of lizards. In Samoa *manaia* is the name of a lizard." Pratt, however, in his "Grammar and Dictionary of the Samoan Language," third edition, 1893, gives *manaia* as "fine-looking, handsome; a good-looking man." The interpretation of this *motive* is greatly to be desired, as it is evidently one of great antiquity and importance. Mr. J. Edge Partington has several

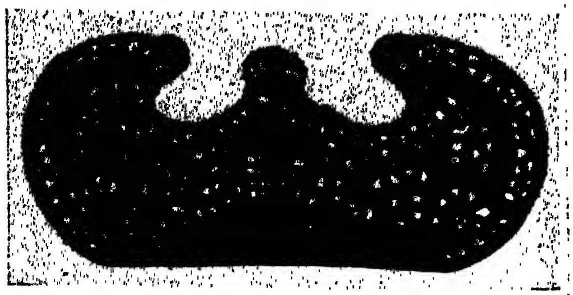

FIG. 2.—Carved *Pare*, or door ornament representing a man, with *manaia* on each side of him.

times attacked the problem (*Journal* Anthrop. Inst., xxix. p. 305; xxx., *Miscellanea*, Nos. 40, 41; *Man*, 1902, No. 17). He believes it to be a lizard, or perhaps a water-snake. The present writer has hazarded the view (*Man*, 1901, No. 55) that it may be a degraded and conventionalised representation of a bird, probably of the sacred bird of the West Pacific, the frigate bird which possesses *mana* (spiritual or magical power) in an eminent degree. The Maori spiral is also called *manaia*, and it appears to be related to the problematical animal. The spiral *manaia* and the less conventionalised *manaia* are associated with human beings on the carvings of the store-houses, and some of these human beings are so grouped as to indicate that they symbolise fertility. It is possible that the *manaia* originally, directly or indirectly, had a similar meaning. If this be so, it would seem as if the carving on these store-houses was a magical formula to ensure the abundance of the crops. Unfortunately, Mr. Hamilton merely says, "the *pataka* was the treasury, and its adornments were not only elaborate and beautiful, but had special significance" (p. 90).

A considerable amount of work yet requires to be done before we can feel that we really understand the symbolism of Maori carvings and the meaning of all the patterns. It cannot be too often or strongly insisted upon that this work cannot be accomplished in European museums; it is necessary for researches to be made on the spot. Let us hope that it be not yet too late.

It seems rather ungenerous to find fault with Mr. Hamilton after all the pains he has taken, but the reader would have been saved trouble if the author had been more careful in his editing. For example, it most frequently happens that the plates on which objects are figured are not referred to in the descriptive text, and *vice versâ*; thus the reader has to hunt through the pages to find the appropriate illustration or description, as the case may be. Sometimes the same class of object is figured on plates some distance apart, and still more troublesome is the case of the illustrations in the text. It is true there are lists of specimens figured in the plates and of illustrations in the text, but the continual turning the pages backwards and forwards to consult these as the text is being read, and the subsequent looking up the illustration, is apt to try the reader's patience.

The study of comparative decorative art will gain greatly by the publication of this work, and we echo the author's expression of sincere thanks to the Board of Governors of the New Zealand Institute at Wellington, N.Z., who have carried out the publication of so costly a work. Messrs. Fergusson and Mitchell, the publishers of Dunedin, also deserve great credit for the beauty of the illustrations and the excellence of the typography.

A. C. HADDON.

THE LONDON EDUCATION BILL.

THE Bill to extend and adapt the Education Act, 1902, to London, passed its second reading on Wednesday, April 29. As was pointed out in the issue of NATURE for April 9, the Bill was introduced by Sir William Anson on April 7, and in referring to the first reading proceedings we summarised its main provisions. As a result of the representations of educationists of different shades of political opinion on the Bill in its present form, the Government made it sufficiently clear during the course of the second reading debate that they were prepared to introduce modifications during the passage of the Bill through the Committee stage.

The central principle of the Bill was defined by the Prime Minister during the second reading debate; it is intended to provide that there shall be a central education authority and other local authorities to which certain powers can be delegated. The central authority is to be the London County Council, and the bodies to which delegation takes place are to be the borough councils. The vote on the second reading affirmed this principle by a majority of 137—163 voting for an amendment that the Bill be read a second time that day six months, and 300 against.

When the Bill is interpreted in the light of what Mr. Balfour has laid down as its fundamental principle, it becomes clear that modifications in its provisions are of great importance, and it is instructive to study the

question from this point of view. First, then, as regards the constitution of the central authority; it is proposed that the new Education Committee for London shall consist of ninety-seven members, of whom thirty-six shall be members of the London County Council appointed by that authority; thirty-one shall be members of the councils of metropolitan boroughs appointed by those councils, Westminster and the City of London appointing two each, and each of the other metropolitan boroughs appointing one member; twenty-five are to be co-opted members representing expert educational opinion, and including representatives from such institutions as the University of London, the City Guilds, the City Parochial Charities, and so on; and for the first five years five members of the existing School Board. The question is, Do these proposals provide for the election of a central education authority on which the London County Council, which has the sole rating power, will have paramount influence? The majority of competent judges think not. There seems no good reason forthcoming for the inclusion of representatives of borough councils, and it is hoped that a change in this connection will be made in Committee. This is the more probable, too, as the proposed education committee is too unwieldy, and will from its size be likely to encourage general debate on educational questions rather than specific and intelligent administration of the work of the schools.

Then there is the question of the duties of the borough councils in their capacity of local authorities with delegated powers. The Bill makes these councils "managers of all public elementary schools provided by the local education authority within their borough," and gives them the appointment and dismissal of teachers in these schools and the custody of the buildings. They are to have, too, the selection of sites for new school-buildings. It is to be hoped that the clauses of the Bill dealing with the duties of borough councils will be greatly changed. It is highly undesirable that the teacher should be regarded as the servant of the local rather than of the central authority, and it is a mistake to run the risk of a lowering of the efficiency of the elementary school teachers in the metropolis by allowing the possibility of local prejudices, relationships, wire-pulling, and what not, to influence the selection of teachers. The London School Board has secured the reputation of having selected its teachers on their merits, and it would be a great mistake to make it possible for the teaching in any London borough to deteriorate because its councillors chose teachers from personal considerations rather than on the score of efficiency. So, also, in the case of the selection of sites for new schools; the central authority would undoubtedly choose these because of their suitability for the purpose; the local councils might conceivably select them for quite other reasons, for example, because a prominent councillor with great influence on the council wished to sell. These points require very careful consideration, and it may be safely predicted that during its passage through Committee the Bill will undergo considerable modification in these directions.

But from the point of view of readers of NATURE it is more important to consider the extent to which the provisions for higher and secondary education contained in the Act of last year are affected by the Bill now before the House of Commons. The present Bill being intended to extend the Act of last year to London, it is clear that the conditions which apply to the rest of the country, so far as secondary and higher education are concerned, are also to hold good in London. The Act of last year repealed the Technical Instruction Acts, and as a consequence the old technical instruction committees are disappearing, and their duties are being taken over by the new education authorities. The same thing will, on the passing of the London Education Bill, take place in London. The present Technical Education Board of the London County Council will be merged in the new central education authority which is to be set up, and from this consideration it is of paramount importance that this new authority should be guided by the same broad principles and actuated by the same lofty ideals as the present Technical Education Board has been. The existing board, with its absence of mere local characteristics, has done excellent work for the secondary and higher education of London, and on these grounds alone the introduction of any local element is to be deprecated.

As Sir Michael Foster said during the second reading debate, the University of London and the new education authority must work together for the better education of the people of London, and the new authority must be interested in university as well as in secondary and elementary education. It may be admitted that the new authority should be interested in all kinds of education from beginning to end, and should be prepared to give generous financial aid to education of university type, but there is a danger in admitting this generalisation which must be avoided. There must be nothing in the direction of delegating powers of managing higher education to local bodies of any kind. University education is in a very real sense a question of national importance. It must be guided by men of culture with the broadest possible catholicity. Education may be one and indivisible, just as London itself must be regarded from the point of view of its education, but the men who are competent to look after the schools of elementary grade are not the persons in whose hands the guidance of higher education may with advantage be left. Because every scheme of higher education depends for its success on the existence of youths possessing a sound general education, no efforts should be spared to secure a satisfactory system of secondary and elementary education in London and the country generally, but it must be persistently remembered that this is but a means to an end. Our boys must be satisfactorily educated, chiefly because without this preliminary training it is impossible to obtain a supply of properly qualified students for our universities and colleges, where, somehow, our manufacturers and merchants must be trained in such a way as to enable them to hold their own with the highly qualified competitors to be found in Germany and America.

It would be an excellent thing for London and for the country if well-equipped and highly endowed university colleges could be provided in several parts of the metropolitan area. But though every effort should be made to ensure the active interest of the local municipal councils in the work of such institutions, their management and government should in no sense be of a purely local nature. There should be a real connection with the State as indicating the national importance of university education, a due representation of existing great universities to enable the colleges of the metropolis to benefit by experience gained in other centres, and also members of the governing body elected by the corporations and persons contributing to the endowment funds.

Thus to point out the disadvantages of saddling university colleges with governing bodies actuated with parochial sentiments is surely quite enough to discourage the supporters of such a policy, and amply sufficient to convince everybody that the most strenuous efforts must be made in a contrary direction. It is only necessary to try to imagine the outburst of ridicule and

indignation which would greet the suggestion that the government of the Universities of Oxford and Cambridge should be placed in the hands of the municipalities of Oxford and Cambridge respectively to see how indiscreet is a proposal made during the second reading debate to give the control of "all kinds of education from the beginning to the end" to the new Education Committee for London. Such an authority will have at least quite enough to do in building up a properly coordinated and duly unified system of secondary and elementary education, and in continuing the excellent work now being done by the London Technical Education Board. It would be in the highest degree unwise to give the new authority any sort of opportunity to interfere, for example, with the procedure of the Senate of the University of London, though, as has been said, it should be made possible for the new committee to show its sympathy with higher education by contributing to the funds of the University of London and of the metropolitan university colleges.

The university college cannot in any narrow sense be a local institution. To attempt to make it so would be the work of an enemy to higher education; indeed, it would be difficult to imagine anything more likely to play into the hands of our competitors than a disposition to place university education under the control of local authorities. Germany, for instance, would probably be highly delighted if this were done.

At present higher education in the United Kingdom largely depends upon private munificence and upon financial aid from municipal authorities. But, when the Government and the people of this country have been educated to understand that the maintenance of universities on a generous scale is of prime importance to the nation's well-being, it will become evident that the only satisfactory solution of a difficult problem is to regard the adequate provision of higher education as an important function of the State. When this is properly appreciated, the universities will be dependent upon State grants alone; they will no longer find it necessary to solicit financial help from individual munificence, or to secure the voting interest of local councillors with the object of obtaining municipal aid.

NOTES.

AT the closing ceremony of the fourteenth International Congress of Medicine, it was announced that the prize of 5000 francs offered by the Moscow municipality had been allotted to Dr. Metchnikoff, of the Pasteur Institute, Paris, and the prize of 3000 francs offered by the Paris municipality to Dr. Grassi, of Rome. The fifteenth congress will be held in Portugal in 1906, when the president will be Prof. Coimbra Costa. Dr. Miguel Bombarda, who will be the general secretary of this congress, is a member of the Royal Academy of Sciences and president of the Royal Academy of Medical Sciences at Lisbon.

THE death is announced of M. Worms de Romilly, formerly president of the French Physical Society, and a member of the committee of the International Association of Electricians.

PROF. E. RAY LANKESTER, F.R.S., has been added to the departmental committee appointed to investigate experimentally and to report upon certain questions connected with the dipping and treatment of sheep.

DR. ROBERT BELL, F.R.S., acting director of the Geological Survey of Canada, is at present in England for the purpose of receiving personally the degree of Doctor of Science which is to be conferred upon him to-day by the University of Cambridge. Dr. Bell was promoted to the directorship of the Canadian Survey more than two years ago, after being associated with the survey department for forty-six years, but it will surprise all who are not familiar with official routine to know that his appointment has not yet been gazetted, and we presume, therefore, that he does not receive the pay of the appointment.

LADY HUGGINS and Miss A. M. Clerke have been elected honorary members of the Royal Astronomical Society.

THE International Association of Botanists has just held its first congress at Leyden under the presidency of Prof. Goebel, of Munich.

THE *Athenaeum* announces the death of Josef Enzenberger, the director of the scientific station of the German South Pole Expedition. Herr Enzenberger was only thirty years of age.

MR. W. H. PATCHELL has been appointed a member of the committee to inquire into the use of electricity in mines in the place of Mr. James Swinburne, resigned.

THE honorary treasurer of the Cancer Research Fund, under the direction of the two Royal Colleges of Physicians and Surgeons, has received the sum of 1000*l*. from Mr. H. L. Florence for the advancement of the investigation of cancer.

THE *Times* correspondent at Wellington, N.Z., points out that unless the next season should prove more favourable than the last, the *Discovery* will remain fast in the ice, and her ultimate abandonment in the Antarctic is possible. It is imperative, therefore, that the relief ship should return.

SOME additional particulars referring to the British Antarctic Expedition have been brought from New Zealand by the s.s. *Paparoa*, which arrived at Plymouth on Sunday with a member of the *Discovery's* crew, and also one of the crew of the relief ship *Morning*. A remarkable experience is related by a young New Zealander named Hare, who set out from the *Discovery* with a party of officers and men to deposit a record at Cape Crozier. He was separated from the party when returning to the ship, and was buried in a snowdrift. After being asleep in the snow for thirty-six hours he was revived by the warmth of the sun, and was strong enough to rise out of the snow and walk to the ship. With reference to some of the work in terrestrial physics, Mr. Bernacchi says in a letter:—"One of the most typical of the magnetograms for the year 1902–3, with *data* for reduction, has been sent home in case something should happen to us before the return of the expedition. The seismograph has been working the whole year, but very few shocks and tremors are recorded. Our largest are on May 25 and on September 22, which seems to correspond with your record on April 18. There are some irregularities in the line which might be due to the Guatemalan earthquake. There are some tremors, however, which coincide with your record. From October 3 to October 8 a great many tremors were recorded. I also have a year's observations of atmospheric electricity."

IN connection with the celebration of the centenary of Dalton's enunciation of the atomic theory, to be held at Manchester next week, the following extract from the presidential address delivered by Prof. J. Emerson Reynolds, F.R.S., to the Chemical Society, at the last anniversary meeting, is of interest:—"This year is the centenary of the announcement, in a tentative form, of probably the most fruitful and valuable of all scientific hypotheses—Dalton's Atomic Theory. On October 21, 1803, Dalton read a paper

"On the Absorption of Gases by Water and other Liquids" before a select audience of nine members of the Literary and Philosophical Society of Manchester. He appended to that paper a statement which, according to Sir Henry Roscoe and Dr. Harden ('A New View of the Origin of Dalton's Atomic Theory,' Macmillan, 1896), is the first published indication of the atomic theory, though the paper was not circulated in the Manchester *Memoirs* until November, 1805. Thus, just 100 years ago, the conception of the discrete nature of matter was formulated, and used to explain the facts then known as to the constant composition of chemical compounds, and the laws discovered by Dalton as to their formation in definite and multiple proportions. This germ of the molecular theory of matter, which now pervades all thought in chemistry and physics, arose, as Nernst truly says, 'by a single effort of modern science, like a Phœnix from the ashes of the old Greek philosophy.' Therefore, physicists as well as chemists are interested in an event of the highest significance in the development of both branches of science. I am glad to know that a special celebration will shortly be held in that great city which claims Dalton as her illustrious son."

The Rumford premium of the American Academy of Arts and Sciences, consisting of a gold and a silver medal, has been awarded to Prof. George E. Hale, director of Yerkes Observatory, in recognition of his researches in solar and stellar physics, and in particular for the invention and perfection of the spectroheliograph.

An International Exhibition of Hygiene, Life-saving, Sports, Fishery, and Ambulance is to be held in Paris from September to November, 1904, at the Grand Palais des Champs-Elysées. Full particulars may be obtained on application to the Commissaire Général, Exposition Internationale de 1904, 3 rue des Moulins, Paris.

The *Lancet* reports that a new building is to be erected in Manila to provide laboratory space for the chemical and biological laboratories and the serum institute. The building will be divided into sixty rooms, and will be 216 feet long and 60 feet wide, having two storeys. The plans of the building have been drawn so as to accommodate all the work within one building, one half of which will be occupied by the chemical and the other half by the biological laboratory.

We learn from *Science* that Harvard University, New York University, and the Bermuda Natural History Society unite in inviting botanists and zoologists to spend six weeks in the temporary biological station provided at Bermuda. The two possible dates of sailing from New York are June 20 and July 4. Circulars and detailed information will be supplied on application either to Prof. C. L. Bristol, University Heights, New York City, or to Prof. E. L. Mark, 109 Irving Street, Cambridge, Mass.

We learn from the *British Medical Journal* that the Croonian lectures before the Royal College of Physicians of London will be delivered this year by Dr. C. E. Beevor on June 9, 11, 16 and 18. The subject will be muscular movements and their representation in the central nervous system. The first course of FitzPatrick lectures will be delivered by Dr. J. F. Payne on June 23 and 25. He has chosen for his subject "English Medicine in the Anglo-Saxon and Anglo-Norman Periods."

A correspondent points out that in each of the embroidered designs reproduced in a notice of East Siberian decorative art (April 16, p. 560) it is possible to distinguish a man's face quite as clearly as the conventional cocks which are supposed to be grouped about the central axis.

A congress commemorative of the fiftieth anniversary of the foundation of the Royal Photographic Society will be held next week. The congress will be opened on Tuesday, May 19, at the New Gallery, Regent Street, at 8.30 p.m., when the president will deliver an address. This will be followed by a conversazione, when the president, Sir William Abney, and council will receive the Society's members and guests. On Wednesday, May 20, at the Society's house, there will be a meeting at which papers will be read, and in the evening there will be a dinner. In connection with the congress there will be a special exhibition at the Society's rooms of objects having interest in the history of photography. The council hopes that this exhibition will represent the various stages of photography from its infancy to the present day. The commemoration of the jubilee will not cease with the congress of which details are given above. It is intended that the annual exhibition shall be distinguished by features which will mark the present year as one of more than usual significance. There will be a special invitation pictorial section in addition to the established pictorial section, and the scientific and technical section will be entirely collected by direct invitation, both having for their object the illustration of the progress and present position of photography.

On May 5 Lord Avebury, the president of the Selborne Society, took the chair at the annual meeting and conversazione. He alluded to several of the many lines of work upon which the association is engaged, to wit, the interest which it is taking in the Home Counties Nature-Study Exhibition, the bird sanctuaries arranged for, and the protection of plants. Lord Avebury claimed that near London plants now needed more looking after than birds, and quoted instances from his own experience; he also pointed out how easy it was for country clergymen to follow in the steps of the great Gilbert White. Sir John Cockburn also alluded to plants and the advantage of the study of flowers to children, saying that in this respect we might all well be children. As chairman of the Nature-Study Exhibition held last year, he wished all success to the new undertaking mentioned by Lord Avebury. Sir George Kekewich said that of all the objects of the Selborne Society, he would put nature-study first. Dr. Bowdler Sharpe gave an illustrated lecture on Selborne, and Mr. Andrew Pears, who recently bought the Wakes, offered a cordial welcome to the members of the Society who are to visit Selborne in June next.

The freedom of the city of Rome was conferred upon Mr. Marconi last Thursday by Prince Colonna, Syndic of Rome. The occasion was marked by much enthusiasm; a conference was held in the afternoon and a banquet in the evening, and from all sides Italians welcomed the opportunity of doing honour to their distinguished countryman. Since then Mr. Marconi has been conducting experiments in Rome and the neighbourhood with, it is reported, very successful results; before leaving Rome he intends to select a site for the high-power station which is to be erected near the city.

Telegrams from Ottawa state that Mr. Fielding, Dominion Minister of Finance, speaking in the House of Commons with reference to the Marconi system, said that the system had not been as successful as had been expected, and that the Government did not propose to make any further contributions towards it. It will be remembered

that last year the Canadian Government made a contribution of more than 16,000*l.* towards the cost of establishing Transatlantic communication. The Canadian Government is, however, still confident of the ultimate success of the system. The delay in getting the Canadian station into successful commercial operation is said to be due merely to a breakdown of a mechanical nature. It seems as if some other difficulties are also being encountered, as one does not hear of any Transatlantic signalling from either of the two American stations.

THE Great Western Railway, following the examples of the London and South Western and North Eastern companies, has decided to run automobile cars on some sections of its line. This method of providing for a more frequent service has been necessitated by the competition of electric tramways, and affords further evidence in support of the view that electric traction is likely to bring about in time a complete revolution in our methods of locomotion. The motor-cars to be used by the Great Western are to be steam driven. A notable feature of the scheme is that provision is to be made for frequent stoppages between the stations to pick up passengers; it is proposed that the cars should stop at all the level crossings—of which there are four on the section between Chalford and Stonehouse, where the first experiment is to be made—and also, if it is feasible, at any points at which foot-paths give access to the line. It is hoped in this way to organise a successful competition with the electric tramway which has been projected and sanctioned parallel to this part of the line. The superiority of electric traction for working of this kind is so well known that one may reasonably expect the Great Western Railway will find it advisable before long to get rid of the steam motor-cars and provide for electrical working over the section, which may pave the way, in the manner that many have prophesied, for the ultimate complete conversion from steam to electricity.

THE electrification of our steam-driven railways proceeds apace; the inauguration of the electrical working of the Mersey Railway, which took place a few days ago, is an event which will probably before long be paralleled by many similar inaugurations all over the country. To the Mersey Railway then belongs, we believe, the honour of being the first steam railway in Great Britain to undergo conversion. Special conditions have in this case hastened the change; the long tunnel under the river made a frequent train service impossible without expensive outlay in ventilation, which the company could not afford. Electrical working was therefore decided upon in 1900, and a contract made with the British Westinghouse Co. to carry out the conversion in July, 1901. In considerably less than two years the work has been completed, in spite of the fact that it involved relaying the whole of the five miles of permanent way, together with putting down the two additional lines of rails to serve as conductors (an insulated return being used) and the erection of a power-house and plant, &c. The tunnel has been cleaned and lighted throughout, and electric lighting installed at all the stations; electricity has, in fact, been adopted for almost every detail of the working. A good deal of the work is naturally of American design, and some of it of American construction. It is to be hoped that as we hear more of other railways being converted, we shall hear less of their using foreign machinery; it is probably inevitable that in the not very distant future our whole railway system will be "electrified," but it is not necessary that this word should be synonymous with "Americanised."

WE regret to announce the death last week of Mr. Clarence Bartlett, who only recently retired from the post of superintendent of the Zoological Society's Gardens in the Regent's Park, which he had held since the death of his father, whom he succeeded, in 1897. Mr. Clarence Bartlett was the second son of Mr. A. D. Bartlett, and was, we believe, brought up in the service of the Zoological Society. During the early "sixties" he was appointed assistant superintendent (and subsequently clerk of the works) to the Gardens, and in 1866 he was dispatched by the council to Surinam to bring home a young manati, which died a few hours before the vessel arrived at Southampton. A more important mission fell to his lot in 1875, when he was granted special leave by the council in order to accompany, as zoological collector, His Majesty the King (then Prince of Wales) to India. From this tour he returned the following year, bringing home in first-rate condition a large number of living mammals and birds, which were housed in the Society's Gardens. Among these was the elephant "Jung Pershad," which lived for many years in the menagerie, and the mounted skin of which is exhibited in the Natural History Museum, where, by the way, it has just been transferred from the zoological to the geological department, in order that it might stand side by side with the skeletons of its extinct relations. Mr. Bartlett appears never to have contributed anything to the scientific publications of the Society. Soon after the resignation of the secretary in the autumn of last year, ill-health and other reasons rendered it advisable that Mr. Bartlett should retire on a pension, but when he left his house in the Gardens it was apparent to all that he had little prospect of living to enjoy this reward of his services.

THE Parliamentary Report of the Meteorological Council for the year 1901–2 has recently been issued in the same form as in the previous year. Among the appendices we find (1) correspondence with the London County Council respecting an inquiry into the occurrence and distribution of fogs in London; the report of the inquiry has been already published. (2) A comprehensive statement of provisions for the supply of information to the public; and (3) an interesting summary of conspicuous meteorological occurrences (with two plates). An application was received from the Royal Meteorologieal Society to assist in providing means in carrying out experiments on the exploration of the upper air by means of kites. In order to facilitate this important investigation the Council agreed to provide the instruments for the establishment of a base station. At the request of the Registrar-General the Council has undertaken the supply of meteorological tables for his weekly, quarterly and annual reports which had been for many years satisfactorily prepared by Mr. James Glaisher, at great personal labour. A considerable number of returns has been received through the Foreign Office from African Protectorates, and the Council has under consideration the publication of an annual summary of the observations from these and other colonial stations; the reduction and tabulation of these important data will entail much additional work and expense. In order to meet the constantly increasing demands upon the public usefulness of the department, both as regards land and ocean meteorology, some revision of the organisation of the various branches has been necessary, including the opening of the office at 8 a.m. for the service of meteorological telegraphy; the Parliamentary grant, however, remains at the same figure as heretofore.

MR. THOMAS H. MEANS, of the U.S. Department of Agriculture, was recently sent to Egypt by the U.S. Secretary

of Agriculture to investigate and report upon the methods of reclaiming alkali lands, with particular reference to the conditions in America. The abandonment of many acres of once fertile land at the time of the Arabian conquest, and the change from the annual flooding to the perennial system of irrigation through canals, has caused the rise and spread of alkali over vast areas in Egypt. The reclamation of large tracts of this kind is being taken up as a business enterprise by British engineers, and the work has proved a large financial success. The conditions met with and the methods used are set forth by Mr. Means in *Bulletin* No. 21 of the Bureau of Soils, U.S. Department of Agriculture.

IN the New Year's number of NATURE there appeared an account of a basil, *Ocimum viride*, a plant which is known to the natives of Nigeria as a protection against mosquitoes. Captain Larymore, by whom this information was first obtained, in a recent letter to the *Times* mentions that he has brought home a plant which he has presented to the authorities of the Kew Gardens, and that it may be seen there. He also states that the natives believe in its efficacy when taken as an infusion in cases of malarial fever. Further evidence is offered in another letter to the *Times* by Sir George Birdwood as to the knowledge widely spread among the Hindus of these qualities of the basils, which occur wild, and are generally cultivated in India. Thus, during the formation of the Victoria Gardens in Bombay, the workmen were attacked both by mosquitoes and malaria, when upon the recommendation of the Hindu manager basil plants were placed round the gardens, with the result that the unhealthy nature of the locality was effectually changed.

PROF. HOYLE (*Manchester Memoirs*, vol. xlvii. No. 9) points out that the cuttle-fish described as *Loligo eblanae* is identical with the one subsequently named *Todaropsis veranyi*, consequently the name of the species should be *T. eblanae*.

IN the January issue of the *Proceedings* of the Philadelphia Academy Messrs. Anderson and Grinnell draw attention to the birds of the Siskiyou Mountains, California, on account of the fact that they exhibit a mixture of types characteristic of two distinct faunas, namely, the moist coast fauna and the dry Sierran fauna.

FROM a distributional point of view, the occurrence in the Philippines of an indigenous representative of the Australasian gum-trees is a matter of considerable interest, and it is therefore satisfactory to find that, according to Mr. J. H. Madden (*Proc.* U.S. Nat. Mus., No. 1327), *Eucalyptus nandiniana*, which is typically from New Britain, also occurs in the aforesaid islands.

AMONG the articles in the *Journal* of the Quekett Microscopical Club, attention may be directed to one by Mr. W. H. Harris on the "dentition" of flies. Although the various forms assumed by the "teeth" of these insects have not escaped investigation, they seem to have attracted but little attention in this country, and the author has therefore done well in pointing out the possibilities of this branch of study. An excellent plate accompanies the paper, in the course of which Mr. Harris expresses some doubts as to whether the true function of the canals known as pseudotracheæ is to convey liquid-food.

THE position in which different birds carry their legs in flight forms the subject of an interesting paper by Captain Barrett-Hamilton in the *Zoologist* for April. In all birds it appears that the tibia, during continuous flight, must occupy a nearly horizontal position, pointing directly backwards. The position of the metatarsi, on the other hand, depends on whether the legs are required to act as a rudder. During flight, birds must have an efficient rudder, and in cases where the metatarsi are very long, as in the heron, and must of necessity be directed backwards, the legs serve this function. On the other hand, in many strong and rapid flyers, especially those which make sharp turns and twists, the steering is effected by means of a long, and frequently forked, tail. Captain Hamilton gives a list of birds exhibiting these correlations, but points out that our knowledge of the subject is still very imperfect, and that careful observation of a large number of species is required. With the exception of the kites and fork-tailed kites, the birds of prey form an exception to the rule.

A USEFUL summary of our present knowledge of leprosy, its ætiology and prophylaxis, is given by Mr. George Pernet in the April number of the *Quarterly Review*. The author discusses the introduction into, and prevalence of, leprosy in the British Isles in the middle ages, the effects of the segregation of lepers, the characters of the disease and of the leprosy bacillus, and the danger of the introduction of the disease into other countries through the importation of coolie, Chinese, or other labourers belonging to races afflicted with this scourge.

AN important report upon the ætiology and pathology of beri-beri has been published by Dr. Hamilton Wright. A specific organism has so far not been discovered, and Dr. Wright has also failed to isolate one. His theory of the nature of the disease is that it is due to a specific micro-organism which remains dormant in certain localities, but that, having gained entrance to the body by the mouth, it multiplies locally in the digestive tract, producing toxins which on absorption into the general circulation cause the various symptoms characteristic of the disease. It is noteworthy also that monkeys kept in a jail where beri-beri was prevalent suffered from a condition resembling the disease in man.

A NEW pattern of electric lamp is being put on the market by the Linolite Company. The filaments, instead of being in ordinary bulbs, are enclosed in short straight tubes about nine inches long; the filament is given a small curl in the middle to allow for expansion. These tubes are mounted end to end in a metallic casing, which serves as a reflector, and also carries the leads and the sockets into which the lamps fit. There is thus produced a single line of light, which is very suitable for certain forms of illumination, such as shop-window lighting, lighting by reflection from the ceiling, decorative illumination, and the like. The lamps are made for all ordinary voltages, and of the same candle-power and efficiencies as ordinary lamps; they are run in parallel for voltages up to 130, but for voltages above 200 the lamps are run in pairs, the two lamps of each pair being in series. The system has been tried on several occasions recently with very satisfactory results.

AT a recent meeting of the Academy of Sciences of Vienna, Prof. Molisch, of Prague, communicated a paper upon phosphorescent bacteria. He has been able to photograph the colonies of a phosphorescent micrococcus by means of its own light. By inoculating large glass flasks of 1–2 litres capacity containing a suitable culture medium with the organisms, a "bacterial lamp" is obtained with which it is quite possible for an observer at a distance of one to two metres to read a thermometer or to see the time of a watch. On a dark night the "bacterial lamp" is visible at a distance of more than sixty paces. It is suggested that such cultures of phosphorescent bacteria

might be employed in powder magazines, or for attracting fish, as the flask might be sealed up and lowered into the water. Under suitable conditions the phosphorescent properties of the cultures last for two to three weeks. It is to be noted that Mr. J. E. Barnard, of the Jenner Institute, some time ago similarly photographed cultures of phosphorescent bacteria, and that at a soirée of the Royal Society two years ago, Prof. Macfadyen and Mr. Barnard exhibited a fine series of cultures of phosphorescent micro-organisms.

THE new issue of the "Psychological Index, a Bibliography of the Literature of Psychology and Cognate Subjects for 1902," published in connection with the *Psychological Review*, has been compiled by Prof. H. C. Warren, of Princeton University, with the cooperation of M. J. Philippe and Dr. W. H. R. Rivers. It includes the titles of original publications in all languages, together with translations and new editions in English, French, and German.

THE third separate issue of the *Annuaire météorologique* is that for 1903, published by the Royal Observatory of Belgium under the supervision of M. A. Lancaster, the director of the Belgian meteorological service. Previous to 1900 there was a single annual publication devoted to astronomy and meteorology. M. Lancaster contributes to the present volume an elaborate article running to 130 pages on the force of the wind in Belgium; it contains an array of useful statistics and several interesting curves.

THE Geologists' Association has arranged an excursion to North Staffordshire for the Whitsuntide holidays. Stoke is to be made the centre from which geological excursions will take place. The members from London will leave Euston on Friday evening, May 29, and return on the following Wednesday evening. Notice should be sent to Mr. E. P. Ridley, Burwood, Ipswich, the excursion secretary, before May 15 by all who intend joining the excursion. An interesting programme of geological work has been arranged, and the daily visits should be enjoyable and instructive.

THE April number of the *Essex Naturalist*, the journal of the Essex Field Club, contains several sensible proposals for a photographic and pictorial survey of Essex, by Mr. A. E. Briscoe; an article on work in the field amongst the fungi, with additions to the flora of Epping Forest made at the fungus foray, 1902, by Dr. M. C. Cooke; and a paper by Messrs. A. S. Kennard and B. B. Woodward on the non-marine Mollusca of the River Lea alluvium at Walthamstow. The journal contains much other interesting material and a number of good illustrations.

MR. JOHN MURRAY has published a third edition of Mr. W. Robinson's "Alpine Flowers for Gardens. Rock, Wall, Marsh Plants, and Mountain Shrubs," which appeared first in 1870. The book has been revised, and should interest all lovers of horticulture in those plants which grow naturally on all high mountain-chains. Since the author states, in the prefatory note to this edition, that "there is not a garden, even in the suburbs of our great cities, in which the flowers of alpine lands might not be enjoyed," the addition of these mountain species to the garden plants usually cultivated in this country should greatly add to the interest of the amateur gardener's work.

THE additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by Miss Ruby Ray; a Lesser Black-backed Gull (*Larus fuscus*) from Port Said, presented by Dixon Bey; a Capybara (*Hydrochoerus capybara*), a Brazilian Cariama (*Cariama cristata*), a Ypecaha Rail (*Aramides ypecaha*) from South America, presented by Colonel Sir T. H. Holdich, C.B.; a Yellow Baboon (*Papio cynocephalus*) from Africa, two Maholi Galagos (*Galago maholi*), a Leopard Tortoise (*Testudo pardalis*) from South Africa, an Indian Rat Snake (*Zamenis mucosus*), two Indian River Snakes (*Tropidonotus piscator*) from India, an Alligator Terrapin (*Chelydra serpentina*), two Alaska Geese (*Bernicla minima*) from North America, two Ross's Snow Geese (*Chen rossi*) from Antarctic America, three Lesueur's Water Lizards (*Physignathus lesueuri*), a Cunningham's Skink (*Egernia cunninghami*), a Gould's Monitor (*Varanus gouldi*), two Limbless Lizards (*Pygopus lepidopus*) from Australia, a Slender Loris (*Loris gracilis*) from Ceylon, two Large Greaved Tortoises (*Podocnemis expansa*) from the Amazons, three Starred Lizards (*Agama stellio*), a Spiny-tailed Uromastix (*Uromastix acanthinurus*) from North Africa, a Mailed Uromastix (*Uromastix loricatus*) from Persia, deposited.

OUR ASTRONOMICAL COLUMN.

COMET 1903 *b*.—From observations made at Windsor, N.S.W., on April 26, 29, and May 1, and communicated by telegraph to the Kiel Centralstelle, Herren M. Ebell and H. Kreutz have calculated the following elements and ephemeris for the comet discovered by Mr. Grigg on April 17:—

Elements.

T=1903 *March* 25·5486 *Berlin M.T.*

$$\left.\begin{aligned} \omega &= 186^\circ\ 40'{\cdot}7 \\ \Omega &= 213\ \ 14{\cdot}5 \\ i &= 66\ \ 29{\cdot}6 \end{aligned}\right\} 1903{\cdot}0.$$

$$\log q = 9{\cdot}71054.$$

Ephemeris for 12h. M.T. Berlin.

1903.	α h. m. s.	δ ° ′	log Δ	Brightness.
May 13	5 36 33	−22 2·8	0·1668	0·51
17	5 57 59	−22 53·9	0·1779	0·43
21	6 18 40	−23 34·9	0·1905	0·37
25	6 38 34	−24 7·2	0·2042	0·31
29	6 57 34	−24 32·2	0·2190	0·27
June 2	7 15 40	−24 51·2	0·2345	0·23

The brightness at time of discovery is taken as unity (*Kiel Circular*, No. 59).

A REMARKABLE ALGOL VARIABLE.—Prof. E. C. Pickering, writing to the *Astronomische Nachrichten*, No. 3866, states that the new Algol variable, 4.1903 Draconis, discovered by Madame Ceraski, is of unusual interest on account of its short period and great range of variability.

An examination of the plates obtained with the Draper telescopes shows that the period is 1d. 8h. 34·7m., and the range of variability 2·4 magnitudes. About half an hour before minimum the brightness decreases at the rate of between 2 and 3 magnitudes per hour, a rate probably greater than any other hitherto discovered. A minimum was predicted and observed at Harvard on March 19 at 16h. 24m. G.M.T.

NEW VALUE FOR THE SOLAR PARALLAX.—In view of the probable publication, in the near future, of the results obtained from observations of Eros, Herr B. Weinberg, of the University of Odessa, has collected about 130 of the more trustworthy values for the solar parallax as obtained by different observers, using various methods, since 1825, and has discussed them in a paper communicated to No. 3866 of the *Astronomische Nachrichten*. From the discussion he has obtained

$$8''{\cdot}8004 \pm 0''{\cdot}00243$$

as his final value for this constant.

INSTRUCTIONS TO OBSERVERS OF THE SUN.—In the April issue of the *Bulletin de la Société astronomique de France* an abstract is given of the first chapter of "Instructions pour l'Observation du Soleil," which will be issued to anyone desirous of systematically recording solar phenomena by the "commission solaire." The instructions give detailed and valuable suggestions on the observation and recording of the positions, size, nature and general details of sun-spots and faculæ, and also suggest the atmospheric conditions which should be recorded concurrently.

The object of the commission is to induce a large number of amateur astronomers, possessing instruments not exceeding 10 cm. in aperture, to participate in the collection of a large quantity of material for the discussion of the eleven-year period of solar variations.

STONYHURST COLLEGE OBSERVATORY REPORT FOR 1902.—This report contains a large amount of useful and detailed information and data as to the observations of meteorological and magnetical phenomena made at the Stonyhurst and St. Ignatius (Malta) Colleges during 1902, together with a report and some notes by Father Sidgreaves.

The sun was observed, at Stonyhurst, on 217 days, and on 110 days drawings of the solar surface were made. The spotted area of the sun observed during 1902 shows a return of solar activity, the figures (unity representing one-five-thousandth of the visible disc) for 1900, 1901, and 1902 being 0·55, 0·29, and 0·33 respectively.

Owing to unfavourable meteorological conditions the stellar spectrographic work was not very fruitful during 1902, but 44 good spectrographs of β Lyræ were obtained, and, as soon as circumstances permit, the results of an investigation of the spectrum of this star will be published.

OPENING OF THE JOHNSTON LABORATORIES FOR MEDICAL RESEARCH IN THE UNIVERSITY COLLEGE, LIVERPOOL.

A WORKING alliance between the forces of science and commerce is a condition of things that has of late been the prayer of many well-wishers to both. It is a happy union which, as we are often told with perfect truth, obtains less in this country than in many others. But in notable degree an exception must be made among our own communities in the case of Liverpool. The opening ceremony performed in Liverpool on Saturday last for the inauguration of the William Johnston Laboratories of the University College exemplified in a remarkable and memorable manner the strength of what is already in fact, and will in a few weeks also be in name, a university of municipal type.

Mr. William Johnston, shipowner, of Liverpool, last year munificently endowed a chair for biochemistry at the College, and also three fellowships for research in physiology, pathology and gynæcology. He has enhanced his splendid and far-sighted gift by now providing a large and well-equipped building for the laboratory purposes, not only of biochemistry, but of tropical medicine, experimental medicine, and comparative pathology. The large block housing these four subjects is built so as to adjoin, and have free internal communication with, the laboratories of physiology and pathology erected five years ago by the Rev. Thompson-Yates. These Johnston Laboratories form a building 90 feet long by from 35 feet to 50 feet wide. They constitute four floors in the entire block, each floor devoted to one separate department of research. It is noteworthy that in this building we find a university building in which there is not a single class-room or lecture-room in the ordinary sense of those words. From basement to roof it is devoted absolutely and exclusively to purposes of research. Tropical medicine is housed in the ground-floor, and is under the direction of Prof. Ronald Ross, F.R.S. The first floor is allotted to experimental medicine, under Dr. Albert Grünbaum, F.R.C.P., and a large proportion of its rooms are already occupied by cancer research. The second floor is entirely given to Prof. Moore's department of biochemistry, and its installation is nearly complete, two workers availing themselves of its equipment and facilities already. The basement, which is, in fact, only half-sunken and extremely well lighted, is entirely given to comparative pathology, under the direction of Dr. Annett.

The character of the arrangement of the fixtures and fittings of the laboratories deserves some notice. The leading idea has been to break up the internal space of the large area enclosed on each floor with the external walls as little as possible by permanent walls. The main floor is therefore cut up into compartments by wooden screens that do not reach the ceiling. These screens serve in many cases to carry, as walls, both shelves and cupboards, but they allow the twelve large windows to distribute light over every nook and corner of the whole. By this arrangement the laboratory is practically divided into bays, in which investigators can work separately, and surrounded on all sides by their working benches or shelves, and yet not obstructing the light of work going on elsewhere. A novel feature is that the floor of the rooms and the tops of the benches are made of polished *lito-silo*, a material which has resiliency, smoothness, and non-absorbent qualities, enabling it to be easily cleaned and disinfected. On all the floors there is a complete supply of water, gas, electric light, electric power, and steam. A lift, as well as a staircase, connects the floors together. The building is warmed by hot water and ventilated by the upper parts of the windows and by extraction shafts arranged down the centre of the rooms.

In the department of experimental medicine, some of the beautiful and costly apparatus provided has been furnished by the fund of 10,000*l.* recently given by Mr. Sutton Timmis for the prosecution of investigation into cancer. Dr. Albert Grünbaum, as the director of the cancer research, has already commenced experimental inquiries in this field on this floor of the laboratories. One of the rooms on the same floor is very fully equipped with electrical therapeutic apparatus of the most modern design.

The whole building forms a set of laboratories giving probably unsurpassed accommodation to the studies which it was raised to house. Certainly we have in the United Kingdom no other so fine laboratories of biochemistry or of tropical medicine. Their erection marks an era in the history of these studies in this country. That these subjects and other kindred direct extensions of physiology and pathology should now demand and obtain spacious accommodation is but one of the many indications that the trend of medical study, and therefore of medical education, has really entered upon a new route. The narrow and facile, but unfruitful and mentally circumscript ways of mere human anatomy are being exchanged for studies of more scientific character, and physical, chemical, zoological, or physiological in method and basis. This will demand, of course, better education in those entering the profession of medicine. It further inevitably connotes a closer association than at present between the art of medicine and pure science. Just as inevitably does it also presage an era probably even more fertile in achievements of biological study than that which we already couple with the names of Darwin and Pasteur.

The formal opening of the new laboratory was presided over by the Right Hon. Walter Long, President of the Local Government Board. A distinguished company attended. In addition to the staff and students of the University College, Mr. William Johnston, the donor, the Lord Mayor of the city, Mr. E. K. Muspratt, Sir John Brunner, Sir Alfred Jones, and many other well-known citizens were present. A large number of visitors, not only from various parts of the United Kingdom, but also from the Continent and America, had gathered to take part in the ceremony. Among these were Sir Michael Foster, Profs. Clifford Allbutt, Armstrong, Halliburton, Schäfer, Waller, Gotch, Stirling, Botazzi, Hausemann, Weigert, Nocard, Grützner, Blanchard, Uhlworm, Eulenberg, Perroncito, Delépine, Woodhead, Ravanel, Steegmann, Lorrain Smith, Macdonald, W. H. Thompson, Trevelyan, Drs. Rose Bradford, Monckton Copeman, Dawson Williams, Seaton, Bulstrode, and many others. In the evening Mr. William Johnston entertained a distinguished company to dinner at the Adelphi Hotel. The President of the Local Government Board, in the course of a vigorous speech on the necessity of progress being maintained in the advance of natural science by research in this country, declared that

science was the best friend any worker could call to his aid, whatsoever might be his particular part and calling in labour. Sir Alfred Jones submitted the toast of "Commerce and Scientific Research," replied to by Sir Michael Foster and Prof. Armstrong. To the toast of "Our Foreign Guests," Prof. Ravanel (Philadelphia), Prof. Nocard (Paris), Prof. Weigert (Frankfort), and Prof. Perroncito (Turin) replied.

THE IRON AND STEEL INSTITUTE.

THE annual meeting of the Iron and Steel Institute was held at the Institution of Civil Engineers on May 7 and 8, and was very largely attended.

The report of the council, read by Mr. Bennett H. Brough, the secretary, showed that in 1902 the Institute had made very satisfactory progress. The membership amounted to 1692, and it was announced that the Institute had subscribed 1000*l.*, payable in five yearly instalments, to the funds of the National Physical Laboratory.

After the usual routine business, the retiring president, Mr. William Whitwell, inducted into the chair the president-elect, Mr. Andrew Carnegie. The first duty of the new president was to present the Bessemer gold medal to Sir James Kitson, which he did in felicitous terms. He then handed the Andrew Carnegie gold medal to Mr. A. Campion for his research on the heat treatment of steel, and a special silver medal to Dr. O. Boudouard, of Paris, for his research on the determination of the points of allotropic change of iron and its alloy. The research submitted by Mr. P. Longmuir, of Sheffield, on the influence of varying casting temperature on the properties of alloys was commended, and a further grant of 50*l.* was made to him to complete the work. Mr. Campion also received a further grant of a like amount to enable him to carry his researches further.

For the scholarships for the current year a large number of applications was received, and after very careful investigation of the claims, the council decided to award four scholarships of 100*l.*, each tenable for one year, to C. O. Bannister (London), to P. Breuil (Paris), to K. A. Gunnar Dillner in conjunction with A. F. Enström (Stockholm), and to J. C. Gardner (Middlesbrough), respectively.

Mr. Carnegie then delivered his inaugural address. It differed widely from all that have preceded it in that it dealt not with metallurgical technology, but with a consideration of the best and most economical methods of obtaining harmonious working between the mechanical and business departments of a concern, and of securing hearty cooperation between the employers and the employed. The address was much appreciated, and the thanks of the Institute were eloquently expressed by Sir Bernhard Samuelson and Sir David Dale.

The first paper read was by Mr. B. Talbot, of Leeds, who described the development of the continuous open-hearth process. Since this new departure in metallurgy was first described in 1900, considerable progress has been made, and a furnace of 200 tons has been in successful operation for some months at Pittsburg. Other furnaces of nearly the same capacity are being erected in Great Britain, in France, and in the United States. In the lengthy discussion that followed, Mr. E. H. Martin, of Pittsburg, adversely criticised the paper, whilst Mr. P. C. Gilchrist, Mr. E. Riley, Mr. Saniter, Mr. F. W. Paul, Mr. G. Ainsworth, Mr. Harbord, and Mr. T. H. Colley spoke in favourable terms of the process.

The meeting then adjourned until May 8, when Mr. Camille Mercader gave an account of the development in the manufacture of railway axles on a large scale accomplished at the works of the Carnegie Steel Company at Pittsburg. With the aid of numerous illustrations, he described a method of producing, by pressing, hollow axles having varying diameters. An animated discussion followed, in which Mr. R. M. Daelen and Prof. Bauerman expressed the opinion that the invention had been anticipated by Ehrhard, of Düsseldorf. Sir James Kitson, Mr. E. Windsor Richards, Mr. S. Lloyd, and Mr. Vaughan Hughes also took part in the discussion.

Prof. J. O. Arnold and Mr. G. B. Waterhouse, of Sheffield, then read an important paper on the influence of sulphur and manganese on steel. The steels examined were those experimented upon by Mr. Brinell. The results of the authors' investigations show that sulphide of iron is deadly in its effect upon steel, whilst sulphide of manganese is comparatively harmless; that the above facts are due to the fusibility, the high contraction coefficient, and the tendency of sulphide of iron to form cell walls or enveloping membranes surrounding cells of ferrite, whilst sulphide of manganese is much less fusible, segregates whilst the iron is at a high temperature, and so collects into rough globules, and very seldom into meshes; that manganese retards the segregation of iron and hardenite, and that what is called pearlite in a normally cooled manganese steel is really a mixture of granular pearlite and unsegregated ferrite; and that the complete segregation of the ferrite in a manganiferous steel can be brought about by very slow cooling, but that such annealing injures the mechanical properties of the steel by lowering the maximum stress and the reduction of area per cent. registered by the unannealed steel. An interesting discussion followed, in which Mr. Stead, Mr. F. W. Harbord, Mr. Vaughan Hughes, and Mr. Sidney Houghton took part.

The next paper read was by Mr. A. Keller, of Paris, who described the application of the electric furnace in metallurgy. This furnace, which is apt to be regarded merely as a laboratory appliance, will, the author thinks, find a place in the iron industry on a large scale. He shows that, although the manufacture of alloys which are little used can scarcely entitle it to rank as a metallurgical appliance, the production of ferrosilicon, which is one of the bases of modern metallurgy, and of iron, steel, copper, and nickel, will permit it to be regarded in this light. The success is the result of carefully controlled operations on a large scale at Livet, in the department of Isère. In the discussion, Mr. A. H. Allen, Prof. Arnold, Mr. B. H. Thwaite, Mr. A. Greiner, Mr. Stead, and Mr. Kilburn Scott bore testimony to the value of the invention.

Mr. C. von Schwarz, of Liége, described the best methods for making Portland cement from blast furnace slag, and showed that there is a wide field open to English blast furnace works for carrying on a profitable industry by the utilisation of their principal by-product. In the discussion Mr. Hutchinson described at considerable length the results obtained at Middlesbrough, and Mr. Stead spoke in optimistic terms of the future development of the manufacture.

Mr. Axel Sahlin next described an ingenious blast furnace top designed not to admit air or to permit gas to escape. Although the blast furnace top has been greatly modified and improved of late years in order to enable the furnace gases to be utilised, it still possesses certain defects which occasionally lead to explosions and other hindrances to efficient working. These drawbacks have been remedied in the blast furnace top described. The construction of this furnace top and its adjuncts ensures immunity from explosions, as no air can enter the furnace at the top, whilst it also provides against gas leaks and accumulations of dust. The success of the new top is demonstrated by its adoption at the Iroquois Iron Works, near Chicago, where the first one was started in 1901, and where fourteen are now working.

Mr. B. H. Thwaite then read a paper on the detrimental effect of flue dust upon the thermal efficiency of hot-blast stoves.

Colonel Cubillo, of Trubia, Spain, submitted an elaborate paper on the open-hearth process, in which he gave calculations of the heat balance of the furnace. The experiments on which the paper was based were carried out in a four-ton Siemens furnace of the new form.

Mr. J. E. Stead submitted a note on the alleged cementation of iron by silicon announced by Moissan and Lebeau. Mr. Stead's experiments show that at temperatures between 1100° and 1200° C. solid iron and free silicon do not combine, and that cementation by silicon is impossible when the iron and steel operated upon are in solid masses.

Prof. Thomas Turner, of Birmingham, submitted an analysis of a specimen of Sussex iron, some 200 years old. The results were as follows:—graphitic carbon, 2·89; combined carbon, 0·32; silicon, 0·62; sulphur, 0·08; phos-

phorus, 0·56; manganese, 0·77; and iron (by difference), 94·76.

The memoirs submitted by the Carnegie research scholars were taken as read, and are open to discussion by correspondence. The paper by Mr. A. Campion, for which the gold medal was awarded, covers seventy-five pages, and is illustrated by fifteen plates. It deals with the heat treatment of steel under conditions of steelworks' practice. The paper by Dr. O. Boudouard, of Paris, for which a special silver medal was awarded, covers eighty pages, and deals with the determination of the points of allotropic change of iron and its alloys by the measurement of the variations in the electric resistance. Results are given for carbon steels, chrome steels, tungsten steels, manganese steels, and nickel steels. The remaining memoirs presented by the Carnegie research scholars deal with the influence of varying casting temperature on the properties of alloys, by Mr. P. Longmuir, of Sheffield, and with the manufacture of tool steel, by Mr. E. Schott, of Berlin.

The proceedings concluded with the usual votes of thanks to the Institution of Civil Engineers, proposed by the president and seconded by Prof. Gowland, and to the president for his conduct in the chair, proposed by Prof. Syed Ali Bilgrami and seconded by Mr. F. Samuelson.

In the evening Mr. Carnegie presided at the annual dinner, which was attended by about six hundred members. The Prime Minister congratulated the Institute on its international and scientific character, and speeches were made by the Duke of Devonshire, Sir H. Campbell-Bannerman, Mr. John Morley, Viscount Ridley, Sir Henry Fowler, Sir James Kitson, and Sir Samuel Chisholm.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The 248th meeting of the Junior Scientific Club was held on Friday, May 8. Mr. R. T. Günther read a paper on "Changes of Land Level," in which he gave an account of researches he had carried out on this subject in the neighbourhood of Naples. The paper was illustrated by slides showing photographs of the coast in this district. Mr. N. V. Sidgwick, Lincoln, read a paper on "The Emission of Heat by Radium Salts."

CAMBRIDGE.—The council of the Senate propose that the Hartley University College, Southampton, should be adopted as an institution affiliated to the University of Cambridge.

The syndicate on the Mathematical Pass Examinations have issued an important report (*University Reporter*, May 12, 1903), in which they recommend a number of far-reaching changes in respect to the geometry, arithmetic, and algebra required in the previous examination. They "are of opinion that it is no longer desirable to insist on the maintenance of Euclid's Elements as a text-book."

The Board of Agricultural Studies report that during the past year 169 students have received instruction in agricultural science in connection with the department. The income of the department, about 3700*l.*, is practically balanced by the expenditure. The need of a permanent building to accommodate the various branches of the work is becoming apparent, and the Board are considering how the need can be supplied.

Dr. Ruhemann, university lecturer in organic chemistry, has been appointed the university delegate to the Congress of Applied Chemistry to be held next month in Berlin.

A bust of the late Dr. John Hopkinson was unveiled at the engineering laboratory on Monday. The vice-chancellor presided, and the speakers included Sir Joseph Lawrence, M.P., Lord Kelvin, Prof. Ewing, and Principal Hopkinson.

DR. CHARLES CHILTON has been offered and has accepted the professorship of biology at Canterbury College, Christchurch, New Zealand, in succession to Prof. Dendy.

THE *Pioneer Mail* states that the site assigned to British India by the Mysore Government for the Indian University of Research to be created in consequence of Mr. J. N. Tata's munificent offer of an endowment measures about 370 acres, is situated in the north-west of Bangalore Cantonment, about four miles beyond the municipal boundary. Besides this gift the Mysore Government have offered five lakhs for initial expenses, and they hold out hopes of further assistance. Prof. Masson and Colonel Clibborn calculate the annual expenditure at 10,000*l.* sterling.

BOOTHAM SCHOOL, at York, was one of the few schools which received medals at the Nature-Study Exhibition last year for their exhibits showing the extent and nature of the work in nature-study done by the pupils. The sixty-ninth annual report of the Natural History Society of this school serves to explain the success then achieved. The study of natural objects is continued throughout the year, and is carefully arranged by the science masters so as to avoid waste of time and effort. A boy with a love for any branch of natural history receives every encouragement, and there can be little doubt of the good effect this sympathetic treatment has on the education imparted.

THE fiftieth report of the Charity Commissioners for England and Wales shows that in the three years ending December 31, 1901, the total amount of charitable bequests in England and Wales reached 6,542,110*l.*, of which 279,890*l.* was intended for education. It has often been pointed out in these columns what large sums are given to higher education in the United States. During the three years dealt with by the Charity Commissioners in their report, benefactions for higher education alone to the extent of 10,392,000*l.* were reported in the United States. That is to say, for every pound sterling given during 1899–1901 for education in all its grades in England and Wales, more than thirty-seven pounds were given by American benefactors for university education alone. The sums devoted by private persons to higher education in the United States were nearly twice as great during these three years as those for every form of charity in England and Wales.

NUMEROUS changes in the regulations for examinations at the University of Oxford have recently been announced. Among the alterations are those in mathematics for the first public examination (pass), in connection with which it is stated that any method of proof will be accepted which shows clearness and accuracy in geometrical reasoning, and that in the case of propositions 1–7, 9, 10 of Book ii., algebraical proofs may be used. The Board of the Faculty of Natural Science has also made similar changes in the mathematical requirements of the Final Pass School, Group C. (1). These changes come into force at the examinations of Michaelmas term, 1904. There are additions to the schedule of mechanics and physics for the preliminary examination of the Honour School of Natural Science, which come into force on and after Trinity term, 1905. The practical examinations, especially in physics, are to be more extensive than hitherto.

A COPY of the report and handbook for the session 1902 of the Technical Instruction Committee of the Essex County Council has been received. It contains detailed information of every department of the work of the committee, and provides another example of the thorough manner in which the county councils have performed the educational duties entrusted to them by the Technical Instruction Acts, now repealed. In connection with the agricultural instruction in Essex, field meetings were held at seven centres. The objects of some of the meetings were to demonstrate the destruction of charlock in field crops by spraying with solutions of copper sulphate and nitrate of soda; the improvement of derelict grass land by manures; no verbal description could adequately convey an idea of the improvement effected by basic slag, which was one of the manures used, on either of these fields, and the farmers attending were strongly impressed by the almost miraculous effect of this manure both on the quality and quantity of the herbage.

THE annual exhibition of the work of pupils in the day, evening continuation, truant, blind, deaf, and special instruction schools of the London School Board was opened last Saturday by Lord Reay at the Examination Hall, Thames Embankment. The exhibits were very numerous and thoroughly representative of the work of children of

all ages, from the lowest classes of infant schools to the evening classes for youths. Though considerations of space only permit particular reference to the section including the science exhibits from the schools of the Board, it may be said that the work shown from the manual training schools, the classes in domestic subjects, the institutions concerned with the physically and mentally defective, and from the classes in art subjects was highly creditable, and served admirably to show the extent and excellence of the work being done in the public elementary schools of the metropolis. The collection of pieces of apparatus to assist the teaching of science was this year much smaller than on previous occasions, the reason being that the offer of prizes for the most successful work was this year discontinued. It was satisfactory to notice that the plan recommended more than once in these columns was on this occasion carried out for the first time, and added much to the convenience of the visitor—we refer to the separation of the work of teachers and that of pupils. Judging from the exhibits, more attention appears to have been given during the past year to work with squared paper and to nature-study subjects, and there were some excellent relief maps made by boys of thirteen which would have been a credit to much older students. Altogether there is good reason to believe that the science work being done in the schools of the London Board, under the direction of Dr. Stewart and Messrs. Hubble and Todd, will lead to the development of habits of careful reasoning and alert observation.

SCIENTIFIC SERIAL.

American Journal of Science, April.—On the gaseous composition of the H and K lines of the spectrum, together with a discussion of reversed gaseous lines, by John Trowbridge. The continuous spectra observed in Geissler tubes when submitted to powerful disruptive sparks are not due to incandescence of the glass walls. The lines obtained coinciding closely with calcium lines, wave-lengths 3968 and 3933 are not due to calcium, but are true gaseous lines. The conclusion is drawn that the method of sifting out air lines from metallic spectra by observing the lines which are apparently common to these spectra and setting down such lines as air lines is a fallacious method.—The Boys radiomicrometer, by C. C. Hutchins. The simplicity and sensitiveness of this instrument indicate its employment in several lines of work, but the difficulty of preparing the small circuit which forms its fundamental part is very great. Details are given of the methods suggested by the author of overcoming these difficulties.—Meteoric iron from N'Goureyma, near Djenne, Province of Macina, Soudan, by E. Cohen. This meteorite belongs to the comparatively rare group of coarsely granular irons, and presents peculiarities of structure which appear to be unique. More than 97 per cent. of it consists of nickeliferous iron, the remaining constituents being schreibserite, troilite, daubreelite, lawrencite, and chromite.—Notes on the collection of Triassic fishes at Yale, by G. F. Eaton.—The mechanics of igneous intrusion, by R. A. Daly. A comparison of the hypothesis of overhead stoping in the formation of magma chambers with the laccolithic theory of crustal displacement, and with the theory of marginal assimilation of invaded formations.—*Brachiosaurus altithorax*, the largest known Dinosaur, by E. S. Riggs.—Some new structural characters of Palæozoic cockroaches, by E. H. Sellards.—The Bath furnace meteorite, by H. A. Ward. This meteorite fell on November 15, 1902, the date on which the orbit of the Leonids cuts that of the earth. The stone consists essentially of olivene and pyroxene, with troilite and metallic sprinklings. There is also present in small quantities a completely colourless, almost isotropic mineral, which is probably maskelynite.—The use of a rotating kathode in the electrolytic determination of the metals, by F. A. Gooch and H. E. Medway. An ordinary platinum crucible, rotated by a small electric motor at a speed of 600 to 800 revolutions per minute, is used as the kathode. Details of experiments with copper, nickel and silver are given, from which it would appear that much higher current densities may be employed than with the usual apparatus without any appreciable loss of accuracy.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, April 22.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The velocity and mechanism of the reaction between potassium ferricyanide and potassium iodide in neutral aqueous solution, by F. G. **Donnan** and R. **le Rossignol**. The velocity of this reaction can be investigated by titration of the iodine liberated; the simplest interpretation shows that it is quinquemolecular.—A microscopic method of comparing molecular weights, by G. **Barger**. Small quantities of the two solutions are introduced into a capillary tube, where they form bi-concave, discoid drops, care being taken to use the solutions alternately, so that each drop of one solution is enclosed between two drops of the other. The capillary tube is then sealed at both ends, and the length of each drop is measured microscopically from day to day until no change in volume is apparent. At this point the solutions are equimolecular.—Note on the spectrum of pilocarpine nitrate, by W. N. **Hartley**. The author states that the curve recently described by Dobbie as that of the ultra-violet absorption spectrum of pilocarpine nitrate is that of nitric acid slightly modified by the alkaloid present.—Isomeric change of dipropionanilide into propionyl-*p*-aminopropiophenone, by Dr. F. D. **Chattaway**. Under the influence of various catalytic reagents, *e.g.* zinc and hydrogen chlorides, dipropionanilide, like diacetanilide and dibenzanilide, undergoes transformation into propionyl-*p*-aminopropiophenone; the latter and some of its derivatives are described.—Note on the formation of di- and hexamethylammonio-cadmium chlorides, by W. R. **Lang**. Dry methylamine and cadmium chloride react at $-11°$ to form a white powder of the composition $CdCl_2,6CH_3.NH_2$. This, when heated to 100°, furnishes a stable substance of the composition $CdCl_2,2CH_3.NH_2$.

Royal Astronomical Society, May 8.—Prof. H. H. Turner, president, in the chair.—The president announced that the council had elected Lady Huggins and Miss Agnes M. Clerke honorary members of the Society.—The secretary read a paper by the Rev. S. J. **Johnson** on a possible cause of the moon's obscurity on April 11, in which the author suggested that the presence of volcanic dust in the earth's atmosphere was the cause of the darkness of the moon's disc during the recent partial eclipse.—Mr. **Lewis** gave an account of a series of measures of double stars made with the 28-inch refractor at the Royal Observatory, Greenwich, during 1902, and described the orbits of some stars of especial interest.—Mr. Bryan **Cookson** gave a short account of his work on the satellites of Jupiter during a recent stay of two years at the Royal Observatory, Cape of Good Hope.—The Astronomer Royal exhibited and explained a series of diagrams of sun-spots and magnetic disturbance observed at the Royal Observatory during the years 1874 to 1901.—Dr. **Rambaut** read a paper on occultations of stars observed at the Radcliffe Observatory, Oxford, during the lunar eclipse, as well as observations of the colour of the shadow, penumbra, &c.—The president suggested certain subjects for discussion, and a short discussion took place on Mr. Percival Lowell's recent proposal of a standard scale of "seeing."—Mr. A. R. Hinks read extracts from a letter from Mr. **Ritchey**, of the Yerkes Observatory, in which he described his methods of developing photographs of nebulæ, &c. Mr. Ritchey stated that with regard to such nebulæ as those of Andromeda or Orion he made his prints from a negative in which the central portions had been reduced. He considered that the star images are smaller on a negative that had been developed extremely slowly.

Anthropological Institute, April 28.—Mr. H. **Balfour**, the president, exhibited specimens of the tools used by the natives of North-West Australia in the manufacture of glass spearheads. The tools consist of a piece of a sheep's leg-bone and of a water-worn pebble of a purely natural shape. The pebble was used in the earlier stages of the spearhead's manufacture, while the bone was used in its final shaping. Mr. Balfour also exhibited a spearhead which had been made with these tools. A full account of the exhibit, illustrated with a plate, will be found in the May number of

Man.—Mr. E. N. **Fallaize** read a paper on the classification of the subject-matter of anthropology. After defining anthropology quite generally as the "science of man," and pointing out how vast was the scope of such a science which must include all that man *is* and all that man *does*, Mr. Fallaize suggested the following classification of the questions with which the science has to deal:—A. Man's place in Nature, including under this head the investigation of man's place in time and man's place in space, the first section (for which the term palæanthropography was suggested) dealing with the origin and descent of man, Tertiary man, the physical types of the Stone, Bronze, and Iron ages; the second with the distribution of mankind, and the classification of races by physical types—general ethnology. Under B. fall all questions dealing with physical structure—anthropography; while C. deals with the functioning of the organs—physiological anthropology—including such questions as heredity, atavism, racial fertility, and the like. Section D. deals with specifically human activities in the following order:—(*a*) gratification of the senses, including dancing and the æsthetic arts; (*b*) gratification of the intellect, the sciences, especially in the earlier stages of their development; (*c*) communication of ideas, language and writing; (*d*) social structure, the individual and the social organism; (*e*) man's intercourse with Nature: (α) material nature—technology; (β) immaterial nature—the study of religion and folklore.—Mr. J. **Gray** read a paper on the measurements of the Colonial Coronation contingent. The paper contained an analysis of the measurements of about one hundred men of the native troops encamped at the Alexandra Palace during the Coronation celebrations. Amongst the races measured were natives of Sierra Leone and the West Coast of Africa, Nigeria, Lagos, Old Calabar, Central Africa and Somaliland; also Fijians, Maoris, Chinese and Singhalese. The mean values of the head dimensions and stature were calculated for each group, and also possible deviations from the mean in other samples. The results were plotted out on a chart, and the conclusions arrived at were that broadly the same race stretches from Sierra Leone to Somaliland, but that towards North Africa the breadth of the head increases. The Asiatic and Polynesian races, such as the Chinese, Fijians, and Maoris, were infallibly distinguished from the African races by the greater breadth of their heads. The measurements of the African races showed remarkably good agreement with Mr. Randall MacIver's measurements of the Berbers, and Sir H. Johnston's measurements of the Central Africans.

Zoological Society, April 21.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Mr. Henry **Scherren** read a short paper dealing with the literature of feather-tracts as found in the writings of Hunter and Linnæus. The author directed attention to a figure in the "Amœnitates" (1766) in which these tracts were shown, and suggested that a passage in "The Garden of Cyrus" proved that Sir Thomas Browne knew of them, and that they varied in extent and position in different birds.—Mr. Oldfield **Thomas** read a paper on some mammals collected by Captain H. N. Dunn in the Egyptian Soudan. Nineteen species were enumerated, of which five were described as new.—In a paper on the geographical distribution of the Mygalomorphæ, an order including the trapdoor spiders and the species formerly grouped together under the comprehensive title Mygale, Mr. R. I. **Pocock** pointed out that the known facts justified the mapping of the world into the following zoological regions:—(1) The Holarctic, including Europe north of the southern mountain chains, North Asia, and North America north of about the 45th parallel of latitude. (2) The Mediterranean, including South Europe, Africa north of the Sahara, and the desert regions of South-western Asia. (3) The Sonoran, including the United States of America south of about the 45th parallel of latitude and the plateau of Mexico. (4) The Ethiopian, including Africa south of the Sahara, South Arabia, and Madagascar. The last-mentioned island ranks merely as a subregion of the Ethiopian. (5) The Oriental, including India, Ceylon, Burma, Siam, and all the Indo- and Austro-Malayan Islands to Australia, "Wallace's line" being non-existent so far as spiders are concerned. (6) The Australian, including Australia and New Zealand, the latter being worthy of recognition as a subregion. (7) The Neotropical, including Central America, apart from the Mexican plateau, the West Indies and South America. These spiders, moreover, furnished very strong evidence in favour of a former union between Africa and South America, and of a connection between the Afro-Mascarene and Austro-Zelandian continents on the one hand, and Austro-Zelandia and the southern extremity of South America on the other.—Mr. **Woodland** read a paper on the phylogenetic cause of the transposition of the testes in mammals.—A communication from Mr. F. F. **Laidlaw** dealt with the marine Turbellaria collected during the "Skeat Expedition" to the Malay Peninsula. In it ten new species were described, three of which were referred to new genera.

MANCHESTER.

Literary and Philosophical Society, April 21.—Mr. Charles Bailey, president, in the chair.—Mr. Spencer **Bickham** read a paper on caoutchouc, in which he described the methods of collection and preparation employed in the different countries where this product is obtained, and remarked upon the geographical distribution of the trees from which caoutchouc is extracted.

PARIS.

Academy of Sciences, May 4.—M. Albert Gaudry in the chair.—Notice on Admiral Ernest de Faulque de Jonquières, by M. E. **Guyou**.—Waves of the second order with respect to their velocity in vitreous media, possessing viscosity, and affected by finite movements, by M. P. **Duhem**.—On some physical properties of trimethylcarbinol, by M. **de Forcrand**. Determinations of the melting and boiling points, specific heat in the solid and liquid states, heat of fusion and volatilisation are given.—On glycuronic acid in the blood, by MM. R. **Lépine** and **Boulud**.—On the ancient lines of the Pliocene and Quaternary beaches on the French coasts of the Mediterranean, by M. Ch. **Depéret**. A preliminary study of the changes of level of the Mediterranean from the Pliocene epoch up to the present time. Four distinct lines of beach can be made out; the early Pliocene at an elevation of 170 to 175 metres, the recent Pliocene at an elevation of 60 metres, early Quaternary at an altitude of 25 metres, and a later Quaternary at an altitude of 4 to 5 metres. The hypothesis of a simple series of negative movements lowering the level of the sea is insufficient to explain these facts.—Remarks by M. Edmond **Perrier** on the sixth volume of his "Traité de Zoologie."—Secular perturbations, by M. Jean **Mascart**.—The period of the sun-spots and the mean annual temperature variations of the earth, by M. Charles **Nordmann**. The work of Köppen has shown that it is only in tropical stations that any connection can be traced between the mean annual temperature and the sun-spot frequency. A study of the observations made at twelve tropical stations shows that the mean annual temperature undergoes a variation the period of which is sensibly equal to that of the sun-spots. The effect of the spots is to diminish the mean terrestrial temperature, that is to say, the curve which represents the temperature variations is parallel to the inverse curve of the sun-spot frequency.—On the twilights observed at Bordeaux during the winter of 1902–1903, by M. **Esclangon**. The hypothesis of finely suspended dust being the cause of the phenomenon would appear to be insufficient. It is more probably due to clouds.—On the Γ function and its analogues, by M. A. **Pellet**.—On the approximation of numbers by rational numbers, by M. Émile **Borel**.—On the relative motion of the work and the tool in cutting the section of a mechanism, by M. G. **Koenigs**.—A transmission dynamometer giving directly the work in kilogrammetres, by MM. **Gaiffe** and **Günther**. An electrical contrivance by means of which the work can be directly read off on an ammeter. The apparatus can be easily arranged to be self-recording.—The theory of electric and magnetic dichroïsm, by M. Georges **Meslin**.—The repulsion of the anode light by the kathode rays, by M. **Salles**.—On metallic diaphragms, by M. Andre **Trochet**. If a plate of platinum is interposed between the two electrodes of a copper voltameter, when the current has attained a certain density, copper is deposited on the platinum. The dependence of this deposit upon the current and the shape of the bipolar electrode is studied quantitatively.—On compounds of aluminium

chloride possessing the function of a ferment, by M. G. **Gustavson.** A study of the action of the intermediate compounds formed in the Friedel and Crafts reaction.—On the action of phosphorous acid on erythrite, by M. P. **Carré.** Phosphorous acid acts towards erythrite as a less energetic dehydrating agent than phosphoric acid. Prolonged action gives a neutral phosphite of erythran, and this is immediately decomposed by water, the acid ester being formed.—Contribution to the study of organic acids, by MM. Œchsner **de Coninck** and **Raynaud.** An examination of the relative stability of the lower members of the fatty acids towards hot concentrated sulphuric acid.—On the heat of formation of some barium compounds, by M. **Guntz.** Starting with metallic barium containing about 98·5 per cent. of the metal, the thermal changes associated with its solution in water and dilute hydrochloric acid have been determined, and the heat of oxidation of barium deduced.—On the chlorides of chlorocinnamylidene and bromocinnamylidene, by MM. Ernest **Charon** and Edgar **Dugoujon.** —The transformations of diphenylcarbonic esters and monosalicylic esters, by M. R. **Fosse.**—On a new diiodophenol, by M. P. **Brenans.** A description of the mode of preparation, properties, and chief derivatives of the diiodophenol (OH) : I : I,I : 3 : 4.—On some new bases derived from the pentoses, by M. E. **Roux.** The new bases, arabinamine and xylamine, are prepared by the reduction of the oximes of arabinose and xylose.—The action of alkalis on glycerol. The application of the reaction to the estimation of glycerol, by M. A. **Buisine.** On heating potash lime with glycerol three different reactions may take place according to the temperature. At 320° the products are potassium acetate, potassium carbonate, water and hydrogen, and a method suitable for the estimation of small quantities of glycerol can be based on the measurement of the hydrogen.—On the existence of arsenic in the egg of the fowl, by M. Gab. **Bertrand.** All parts of the egg were found to contain appreciable amounts of arsenic. These results confirm the existence and probable function of arsenic in all living cells. —The influence of the radium rays on fertilised eggs, and on the first stages of development, by M. Georges **Bohn.** —On the formation of melanic pigment in the tumours of the horse, by M. C. **Gessard.** The abnormal production of black pigment in the healthy or morbid tissues of man is rare, but is very common in the horse. The chromogenic substance is tyrosine, the oxidation of which by tyrosinase which is present gives the colouring matter.—The law of action of trypsin on gelatin, by MM. Victor **Henry** and Larguier **des Bancels.** The action was followed by the changes produced in the electrical conductivity.—On the increase in weight in white mice, by Mdlle. M. **Stephanowska.**—On a new secreting apparatus in the Coniferæ, by M. G. **Chauveaud.**—The development and anatomical structure of the seminal tegument in the Gentianaceæ, by M. Paul **Guerin.**—A respiratory hygrometer, by M. Pierre **Lesage.** A modified form of dew-point hygrometer. It has been found that the pressure of the water vapour in expired air does not correspond to the saturation pressure, and varies with state of the man.—The germination of the spores of truffles, the culture and characters of the mycelium, by M. Louis **Matruchot.**—On the echinitic fauna of the Gulf of Suez, by M. R. **Fourtau.**—On the closed basins of the Swiss Alps, by MM. Maurice **Lugeon,** Maurice **Ricklin,** and F. **Perriraz.**

DIARY OF SOCIETIES.

THURSDAY, MAY 14.

ROYAL SOCIETY, at 4.30.—The Combination of Hydrogen and Chlorine under the Influence of Light: P. V. Bevan.—On the Photo-Electric Discharge from Metallic Surfaces in Different Gases: Dr. W. Mansergh Varley.—The Elasmometer, a new Interferential Form of Elasticity Apparatus: A. E. Tutton, F.R.S.—Meteorological Observations by the Use of Kites off the West Coast of Scotland, 1902: Dr. W. N. Shaw, F.R.S., and W. H. Dines.—On the Radiation of Helium and Mercury in a Magnetic Field: Prof. A. Gray, F.R.S., and Dr. W. Stewart; with R. A. Houston and D. B. McQuistan.—A New Class of Organo-Tin Compounds containing Halogens: Prof. W. J. Pope, F.R.S., and S. J. Peachey.—The Xanthophyll Group of Yellow Colouring Matters: C. A. Schunck.

ROYAL INSTITUTION, at 5.—Proteid-Digestion in Plants: Prof. Sidney H. Vines, F.R.S

MATHEMATICAL SOCIETY, at 5.30.—Generational Relations Defining an Abstract Simple Group of Order 32736: W. H. Bussey.—Points in the Theory of Continuous Groups: Dr. H. F. Baker.—On Fermat's Numbers: Lieut.-Col. Cunningham and Messrs. Western and Cullen.

SOCIETY OF ARTS, at 4.30.—The Province of Assam: Sir James Charles Lyall, K.C.S.I.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Applications of Electricity in Engineering and Shipbuilding Works: A. D. Williamson.—Electric Driving in Machine Shops: A. B. Chatwood.

FRIDAY, MAY 15.

ROYAL INSTITUTION, at 9.—The Origin of Seed-Bearing Plants: D. H. Scott, F.R.S.

MONDAY, MAY 18.

SOCIETY OF ARTS, at 8.—Mechanical Road Carriages: W. Worby Beaumont.

TUESDAY, MAY 19.

ROYAL INSTITUTION, at 5.—The Astronomical Influence of the Tides: Prof. G. H. Darwin, F.R.S.

ROYAL STATISTICAL SOCIETY, at 5.—The Growth and Direction of our Foreign Trade in Coal during the Last Half Century: D. A. Thomas, M.P.

WEDNESDAY, MAY 20.

CHEMICAL SOCIETY, at 5.30.—Isomeric Partially Racemic Salts containing Quinquevalent Nitrogen. Part xi. Derivatives of *dl*-Methylhydrindamine and *dl-neo*-Methylhydrindamine. Isomeric Salts of the Type $NR_1R_2H_3$: G. Tattersall and F. S. Kipping.—The Conditions of Decomposition of Ammonium Nitrite: V. H. Veley.—Note on the Action of Methylamine on Chromic Chloride: W. R. Lang and E. H. Jolliffe.—The Action of Liquefied Ammonia on Chromium Chloride: W. R. Lang and C. M. Carson.—Cholesterol. A Preliminary Note: R. H. Pickard and J. Yates.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Exhibition of Pond Life.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—The Relation of the Rainfall to the Depth of Water in a Well: Charles P. Hooker.—The Frost of April, 1903: William Marriott.

THURSDAY, MAY 21.

ROYAL INSTITUTION, at 5.—Proteid-Digestion in Plants: Prof. S. H. Vines, F.R.S.

FRIDAY, MAY 22.

ROYAL INSTITUTION, at 9.—Dictionaries: Dr. J. A. H. Murray.

THE PRINCIPLES OF DISEASE.

The Prevention of Disease. Translated from the German. With introduction by H. H. Bulstrode, M.A., M.D. Pp. xviii+1063. (Westminster: A. Constable and Co., Ltd., 1902.) Price 31*s.* 6*d.* net.

IN all studies we are turning back to remoter and remoter causes, and to the investigation of origins; but, as we abstract and abstract, we are apt to get vaguer and vaguer, more and more are individual features merged in types, and in medicine we may find ourselves reduced at last to the emptiness of general counsels for a temperate and wholesome life. Nevertheless, the modern physician cannot be content with the knowledge that the patients under his care are victims of phthisis, of Bright's disease, of failing heart, of premature senile decay, and so forth, without a desire to learn the nature and direction of the processes by which such changes are initiated. As in but few instances he has discovered these small beginnings he is discontented; and it is well that he should be so. Our ancestors did not fail to see that diseases are moving things, so active that some demon or evil principle might be behind them; but this conception of activity, effective enough for instant purposes, contained no adequate notion of remote or latent causes. Some such notions may be traced in the ancient doctrines of the temperaments or diatheses, but were speculative and comparatively barren. Initial causes were, as we should expect, first observed and revealed in the infections, when a definite external pathogenic factor enters into a healthy or apparently healthy person; but even such events would seem to be very inconstant in their occurrence. Of two men exposed to such an attack, one would betray no sign of suffering, while the other would fall ill; an inconstancy indicating that the causation of an individual case of infection consists of far more than the intrusive element itself, which in some cases impinges upon a series of cooperating, in others of antagonistic causes. And if the patient succumbs, the outbreak of disorder is not immediate; a variable but specific interval elapses before its first manifestations. Now if from the recognised infections we turn to other diseases, we try to discover if some of these also arise from incidental agencies of a more occult kind, but having also their latent periods and gradual initiations. Others, again, may not be attributable to external elements, scarcely even as secondary and accelerating causes; but arise as later terms of processes implicit in the organism itself, perhaps even from the embryo.

Now the more definite and prevalent the outer causes, as in the more notable infectious diseases, the better is our position, if we can discover the laws of them, to take preventive and defensive measures on an extensive scale, and to entrust them to public physicians acting on behalf of individuals only as members of a community. On the other hand, the more a disease is the outcome of individual and peculiar proclivities, the less are such public and universal precautions available against it. Public health may be secured by universal rules and enterprises, but the health of individuals, so far as it involves a study of the constitution of each one of them, must be a matter of private practice; though diseases such as phthisis, which arise from a cooperation of general and personal factors, need for their prevention a combination of public and private means.

In respect of epidemic infections, which can be studied on public lines, and have more definite causes and periods, much has been done in the way of prevention since the time of those first medical officers of health, the fetishman or voodoo; but, as Dr. Bulstrode says in his able preface to the volume before us, similar investigation of remote and initial causes, and the preventions to be based upon them when detected, have made but little way as yet in constitutional diseases. Indeed, Dr. Bulstrode goes so far as to suggest, justly as we think, that one of the uses of this book on the prevention of disease in its broader and yet more intimate sense, will be to force upon the notice of physicians that, meritorious as it is to stem the tide of established maladies, this function would be less and less in demand if our insight into and means of detection of their incipient terms were more largely developed. It is the chief merit of the work before us that, perhaps for the first time, our conception of preventive medicine is carried in a formal and imposing way beyond the sphere of the infections; and the first comprehensive attempt is made to apply preventive principles to the initial phases of all diseases.

The dangers of such an enterprise are obvious; when we leave conspicuous and specific phases of change, and seek for the more abstract and universal springs of disordered health, we run the risk of losing not only colour and vivacity, but grip and precision also. As we empty our conceptions of individual characters, we may lapse into platitude. In the construction then of a pioneer work on these broad lines, and on these remoter and vaguer conditions of disease, especial care should be taken to avoid such triviality, and to convince the reader that in tracing rivers to their sources the explorers have not lost themselves in a multitude of shallow rills and in a confusion of forests and watersheds. In this somewhat uncomely, and, seeing that illustrations were not needed, expensive volume, we think that the dangers we have indicated have not been avoided altogether. In a cooperative work we expect to find writers of very wide differences of merit; some good, some middling, some really trivial: but the jealous regard for precision and touch with nature which, as we have seen, should be the note of such a work, and the antidote to its summary methods, has not always been enforced by the editors. The introductory article on the history of the prevention of disease among the Hindoos, Chinese, Israelites, &c., was scarcely worth doing on so small a scale, and is certainly slight enough: it contains some interesting points; but others are not thought out, many statements are loose, and not a few

positively erroneous. We find, for example, the amazing statement that the *speculum vaginae* was unknown until a hundred years ago; yet of medical historians who could forget, at least, the *locus classicus* in Paul of Egina concerning this instrument in its valve and screw form, and the instructions for its use? In the same article we have dubious quotations from such still more dubious authors as "Tralus" (*sic* in text and index; for Alexander of Tralles?) and "Calomella" (a version redolent of the shop!), slips which do not reinforce our confidence in the author's general accuracy. If the editors are to blame for some of these oversights, they are surely still more to blame for passing sentences either so ignorant or so unfair as this:—

"It has been shown, by Koch and others, that malaria is conveyed largely, if not entirely, through the instrumentality of certain mosquitoes."

"Koch and others" is good. "Surmise," again, is far too feeble a word to indicate the epoch-making theory and practice of Semmelweiss in puerperal fever. The next article, by one Martins of Rostock—so he is called in the contents, index, and in all cross references—is a far abler one. We are disposed to attribute it to Prof. Martius. That we ourselves, and we are glad to observe Dr. Bulstrode also, differ profoundly from him in some important respects is not, of course, to be pressed to his disadvantage.

It would be impossible for us, even within limits far wider than the present, to discuss each of the many articles in turn, or, indeed, within the limits of leisure and patience, to read them all critically. For the most part the bread is too deeply drowned in sack. In many chapters there is little but some character of attenuation to distinguish the contents from the therapeutical sections of current text-books; while there is much to remind us of the lip medicine of the student, with his common formulas, such as that "the patient is to be put upon a light and nutritious diet," &c. In turning to the index for fresh light upon the initial causes of particular maladies, we find too often nothing, as in the case of gall-stones, pernicious anæmia, acute rheumatism,[1] scurvy and certain other maladies in which new knowledge seems to promise to be of high preventive value; or we find such vapid paragraphs as are given to arterial diseases, senile decay, dilatation of the stomach, &c.; or, again, equivocal names, such as "anæmia" undistinguished from chlorosis and other particular kinds of impoverished blood. Thus too often general views are attained only by slurring over essential differences. We have sought in vain, moreover, for recent observations on the geographical distribution of cancer; and for the significant fact of the prevalence of primary cancerous growths upon the surfaces of the body.

We are sorry we cannot speak with more appreciation of this important book; but we feel, as Dr. Windscheid, of Leipzig—the able author of the chapter on the prevention of diseases of the nervous system—evidently does, that it is difficult to avoid falling, as some of his collaborators certainly have done, between the stool of specific detail and that of general gossip. However, that a work with such aims should appear at all is satisfactory; we could scarcely expect the first attempt to be one of full achievement. The translations, if slipshod at times, are, as the editors claim for them, readable English enough; but the editors have failed too frequently, whether in the text or by means of notes, to modify facts and opinions, as, for instance, in respect of the diet of the working classes, hours of labour, the management of schools and so forth, which, however true of German societies, are inapplicable to English conditions.

T. C. A.

[1] For the recent views of the causation of rheumatism we searched the index and found a reference to p. 112, but failed there to find any such discussion. There are many errors in the index.

ZOOLOGY FOR ARTISTS.

Anatomie artistique des Animaux. By Éd. Cuyer. Pp. xii+300; 143 figs. (Paris: J.-B. Baillière et fils, 1903.) Price 7.50 francs.

DOZENS of treatises on the anatomy of the human body have been written for the use of artists, but this is the first systematic attempt to place a knowledge of the structure of the more common mammals at their disposal. During the last ten years, M. Édouard Cuyer, who is a lecturer on anatomy at l'École nationale des Beaux-Arts, has been in the habit of adding to his ordinary lectures on the structure of the human body a number dealing with the anatomy of the mammals more commonly drawn by artists. The preparation of these lectures entailed much research, and hence this work, which is based on the lectures, not only treats comparative anatomy from a new point of view, but also contains a number of original observations. In this country M. Cuyer is best known as an illustrator of anatomical subjects; in this *rôle* he stands unrivalled, and the drawings which he has supplied for the work under review are the most accurate representations to be found in any work dealing with the anatomy of mammals.

No question has been more debated than the value of anatomy as an aid to art. Ruskin's dictum was that an artist should paint what he could see, not what he knew he ought to see; he even went further, and held that art was debased by a knowledge of anatomy. However that may be, one might have seen, a few years ago, Onslow Ford, Briton Rivière, and J. M. Swan, three of the most truthful and successful animal modellers and painters this generation has produced, dissecting and drawing, hour after hour, in the prosectorium in the Zoological Gardens at Regent's Park. M. Cuyer cites the great animal painter Barye as an example of an artist whose work has gained in force and precision by his accurate knowledge of anatomy. Anyone familiar with either the work of Barye or Swan will recognise that they are real zoologists who epitomise in their modellings and drawings the living and essential nature of the animals portrayed.

M. Cuyer presumes that the student is already familiar with the structure of the human body, which is made the basis for a comparative study of anatomy.

At first sight the human body may appear too highly specialised to serve as an efficient type for comparison, but in reality this is not so. The fact that the ordinary mammal presents a side view to the artist while the human body is usually studied from the front is merely one of detail. The chief points in which the human and ordinary mammalian bodies differ relate to the head and limbs, and the limbs of man are more primitive in structure, less specialised and evolved than those of the ordinary domestic animals. The evolution of the quadrupedal limbs forms an interesting study in high specialisation of one or more digits and retrogression in others, and it is from this standpoint that M. Cuyer deals with the anatomy of the extremities of the domestic animals. Through the limbs of the cat, dog, pig, ox and horse he traces the gradual retrogression of the clavicle, muscles of supination and pronation, ulna, and lateral digits, and shows how these modifications are due to the specialisation of the limbs as organs of pure support instead of mixed instruments for prehension as well as support. His discovery of a vestige of the *pronator radii teres* in the horse is of great interest; how many millions of years is it since the ancestor of the horse required to supinate or pronate its arm?

In the hands of the artist the whole perspective of anatomy becomes changed, and it would be for the benefit of our text-books if the pure zoologist sometimes looked at his work with the eye of an artist. M. Cuyer recognises the fact that an observation on the dead animal remains dead until it is transferred to the living, and the great merit of his work is that he lays a greater emphasis on the actions than on the attachments of muscles. External form, expression, and action are the points which an artist seeks to understand; hence the systems of the body dealt with here are the skeleton, muscles, proportion, and movements. Everyone must have noticed the marked difference in form between the haunches of an ox and of a horse, yet it is doubtful if any of our modern comparative anatomists could indicate the meaning of these structural differences.

Marey's work forms the basis of the chapters in which are described the various characteristic movements of the horse. In dealing with the proportions of the ideal horse M. Cuyer holds the common-sense opinion that there is no absolute standard such as that suggested by Bourgelat, who held that the length of the body from the shoulder to the rump should measure the same as the height at the withers. The observations of Colonel Duhousset on fifty Arabian horses are quoted; in ten of these the length and height were equal; in twenty-six the height was decidedly the greater measurement; in fourteen the length was the greater.

M. Cuyer, as is the habit with many French scientific writers, quotes no author outside the limits of his country. On p. 33, for instance, he refers to an observation by Marey, made in 1890, that there is no correlation between the power of flight and the development of air cells in birds. This matter was fully studied and accurately described in the well-known work of John Hunter a century before Marey was born.

HINDU CHEMISTRY.

A History of Hindu Chemistry from the Earliest Times to the Middle of the Sixteenth Century A.D., *with Sanskrit Texts, Variants, Translation and Illustrations.* By Prafulla Chandra Rāy, D.Sc., Professor of Chemistry, Presidency College, Calcutta. Vol. i. Pp. lxxix+176+41. (London and Oxford: Williams and Norgate, 1902.) Price 12*s.* 6*d.* net.

THE origin of Hindu chemistry is hidden in the obscurity of past ages. It is certain that the alchemists of western Europe owed much of their learning to the Arabs. M. Berthelot, in "Les Origines de l'Alchemie," has shown that the Arabs derived many of their ideas from the Greeks, but Dr. Rāy quotes other weighty opinions, and furnishes additional evidence in support of the view that the Arabs were even more indebted to the Hindus. In the eighth century the Caliphs of Bagdad ordered several of the medical works of India to be translated, and both then and later learned Arabs were sent to India to study science. Not content with pointing out these facts, Dr. Rāy reminds his readers that the Greeks themselves derived their knowledge of many things from the Hindus, who had, for example, solved the 47th proposition of the first book of Euclid, 200 years before the birth of Pythagoras. Relying on this and similar evidence, Dr. Rāy places the date of the works of Vāghbata at some time before the eighth century A.D., and the surgical and medical treatises of Susruta and Charaka many centuries earlier, in pre-Buddha times. The last-named book, however, "embodies the deliberations of an international congress of medical experts, held in the Himālayan regions," and the fourth veda, the Atharva-veda, appears so archaic by its side that it must be older by "probably a thousand years or more." In the Atharva-veda "plants and vegetable products in general are fully recognised as helpful agents in the treatment of diseases," and at that period (say 2000 B.C.) alchemical notions had already gathered round gold and lead, gold being regarded as the elixir of life, and lead as the dispeller of sorcery.

The progress of chemistry in India, if it were judged only from the manuscripts still in existence, would appear to have been bound up with the study of medicine. Preparations of mercury and other metals were described, and their use recommended in various diseases, several centuries before the time of Paracelsus, the internal use of the black sulphide of mercury dating from the tenth century A.D. at the latest. There are, however, many signs that the study of metals had already progressed far beyond the knowledge required by the medical practitioners.

Thus in "Rasarnava" (twelfth century) we read "copper yields a blue flame . . . that of the tin is pigeon-coloured; that of the lead is pale tinted," and as another example:—

"A pure metal is that which, when melted in a crucible, does not give off sparks nor bubbles, nor spurts, nor emits any sound, nor shows any lines on the surface, but is tranquil as a gem."

Then there is the Kutab pillar near Delhi, a wrought-iron column which weighs ten tons, and is some 1500

years old, the huge iron girders at Puri, the iron-roofed temple porch at Kanurac, and other relics which show the ancient familiarity of the Hindus with this metal. In the fourteenth century brass and bell-metal were stated to be alloys, and zinc, copper and tin to be metals. The manufacture of gold jewellery is also of great antiquity in India.

Dr. Rāy has ably carried out his task of proving that the ancient lore of the Hindus was far in advance of that of the rest of the world, China excepted. The reader who is unversed in Sanskrit may perhaps be pardoned if he sometimes loses himself for a moment in the maze of Hindu names, and it will be well if his "discerning faculty is nimble and agile, and can suddenly surround a proposition." A glossary would be useful, but could scarcely add to the interest of the volume. The second volume, promised when Dr. Rāy has examined further manuscripts, will be welcome.

T. K. R.

OUR BOOK SHELF.

The Soil: an Introduction to the Scientific Study of the Growth of Crops. By A. D. Hall, M.A. Pp. xiii + 286. (London: J. Murray, 1903.) Price 3s. 6d.

WHEN one who has been for many years both a teacher and an investigator commits to paper the facts and ideas which have formed the substance of his later courses of instruction, we expect a very useful book, and in the present instance we are certainly not disappointed. The book before us takes a wide scope; it deals with the origin of soils, their physical properties, their chemical properties and composition, methods of analysis, the living organisms within the soil, the causes of fertility and sterility, soil types and the natural flora belonging to each. The book is primarily intended for college students. Owing to its wide scope it does not attempt to treat any part of the subject in an exhaustive manner; it possesses, however, the great merits of originality and suggestiveness, virtues which are not always to be found in the formal text-book. A prominent feature of the work is the introduction of the results of investigations carried on by the author while principal of the Agricultural College at Wye. English books on scientific agriculture have hitherto been so necessarily filled with descriptions of foreign researches that any results obtained under English conditions have an exceptional value, and appeal to the farmer in a special manner.

In a work dealing with so many subjects, there are naturally some points open to criticism. The author seems to hesitate in attributing some of the physical properties of soil constituents to their colloid nature, and thus leaves unexplained the enormous amount of hygroscopic water held by humic matter. The indigo method of determining nitrates is mentioned as one that may be used for determining nitrates in soil extracts; the method is, in fact, unsuitable for this purpose, as it gives results much below the truth owing to the presence of organic matter. Nitrification is occasionally spoken of as a kind of "fermentation"; objection may surely be taken to this description. Fermentation is a word of wide meaning, but it surely should not include the oxidation of inorganic matter by a living organism. The chapter dealing with the power of soils to retain various bases and acids is full of interest, yet the theory is incompletely stated, the results of the German, French, and some English investigations on the subject being unnoticed. The laws governing the diffusion of salts, and the results of their molecular diffusion in a moist soil, are also not noticed. The cause of the sterility of alkali lands, and their proper treatment, are, however, well discussed, and many excellent illustrations of the subject are introduced from the experience gained in Egypt.

In a book dealing with many details some slips will inevitably occur; the most important one in the present case is that King's determinations of nitrates in fallow soil appear as determinations of nitrogen as nitrates; the quantity of nitrates present is thus unintentionally much exaggerated.

The concluding chapters on fertility and soil types exhibit most fully the thoroughly practical character of the author's teaching, and will be much valued by many readers. The book is sure to meet with a favourable reception.

R. W.

Electrical Problems for Engineering Students. By W. L. Hooper, Ph.D., and R. T. Wells, M.S. Pp. v+170. (Boston and London: Ginn and Co., 1902.) Price 6s.

THIS is a collection of numerical and mathematical exercises in electrical engineering, starting from the most elementary beginning and ending in the more difficult problems presented by the design and working of direct and alternating current dynamos and motors. The exercises have been tested by the practical experience of the authors at Tuft's College, Mass., and are such as would form a useful accompaniment to a two or three years' lecture and practical course. A distinctly good feature of the book is the number of examples requiring graphical solutions, which cannot fail to impress upon the student the advantages gained by plotting curves. It is always an objection to exercises of this sort that they tend too much to the purely arithmetical and academic side of the subject; thus, many of the problems on subjects which are treated only in an elementary manner in this book are little better than arithmetic sums. For example, in the twelfth chapter, on electrochemistry, there are eleven problems, which are all practically simple proportion sums, and we doubt if the student would gain much more by solving them than he would by solving an equal number of problems on, say, the number of able-bodied men and boys required to till a field. But, if the book be used with discretion, these drawbacks will be lessened, and provided the student is taught in other ways to think about and really understand his subject, these exercises will serve to give him a facility in attacking numerical problems as they arise. The book should prove a useful aid to students and teachers of electrical engineering.

M. S.

Open-Air Studies in Bird Life; Sketches of British Birds in their Haunts. By C. Dixon. Pp. xii+280; illustrated. (London: Griffin and Co., Ltd., 1903.) Price 7s. 6d.

MR. DIXON appears to consider that the appetite of the British public for books on the birds of their own islands is insatiable, and as he seems to find a publisher for all his works on this subject, he is perhaps justified in this opinion. In the present instance the subject is treated from a standpoint somewhat different from the one usually adopted, the birds being described in connection with their environment or "station," instead of systematically. Although this mode of treatment necessarily involves a certain amount of repetition (as in the case of the sparrow and the lapwing), it permits the descriptive side of the subject to be relegated somewhat to the background,

and greater prominence given to habits. So far, however, as we can see, the author appears to have recorded little or nothing new in regard to the latter, and we venture to think that he has missed an opportunity of giving fuller detail as to adaptation to environment, especially as regards coloration. Neither is he to be congratulated as regards his style in many parts of the work, as witness the following sentences in the description of the bearded tit (p. 184):—"The family characters are the same as the generic ones. It is found in various parts of Europe and Asia." It may be also pointed out that "Obb" (p. 261) is not the name of a well-known Siberian river. Again, the introduction of the word "Raptores" in connection with a cut on p. 84 is unnecessary and puzzling, when it is not, so far as we can see, used in the text. And this reminds us that a glossary of *eight* items seems strangely inadequate in a work where a considerable number of technical terms are necessarily employed, for we quite fail to see why it is necessary to explain the meaning of "aftershaft" and leave the reader to find out the signification of "primary."

As regards the illustrations, we have nothing but commendation to bestow, the full-page plates by Mr. Whymper—and especially the one of kingfishers—being exquisite delineations of bird-life. We notice, however, that the small text-figures of birds' heads are for the most part the well-known cuts of Swainson, which were used *with full acknowledgment* by Prof. Newton in his "Dictionary of Birds." Why, we may ask, has the author thought fit to depart from this excellent practice, and to publish the cuts in question as though they were original? R. L.

The Bermuda Islands. By A. E. Verrill, Yale University. (Published by the Author, New Haven, Conn., U.S.A., 1902.)

IN this book, reprinted from the *Transactions* of the Connecticut Academy of Sciences, Prof. Verrill gives an account of the Bermuda group which is intended to subserve four distinct purposes; first, that of a general guide-book on the history, structure, and productions of the islands, for the use of visitors; second, of an introductory text-book to the study of the natural history of the archipelago; third, of a record of the more important changes in the flora and fauna already caused by man; and, lastly, that of a general introduction to a series of more technical memoirs, by the author and other naturalists, on the natural history and geology of the islands, now in course of publication. The present volume includes a general description of the islands, an account of their physical geography and meteorology, a sketch of their discovery and early history, and an account of the animals and plants introduced or exterminated since their discovery by the Spaniards about 1510. The last part of Prof. Verrill's work is of special value, for, so far as appears, no human being had set foot on the islands before that date. Accounts of the geology and marine zoology of the group are promised in a later volume. The book is illustrated by thirty-eight excellent plates, and a large number of cuts, and a valuable bibliography is appended.

La Pratique des Fermentations industrielles. By E. Ozard. Pp. 168. (Paris: Gauthier-Villars, n.d.) Price 2.50 francs.

THIS book is intended specially for the use of brewing chemists. The author gives the essential principles underlying the various fermentation processes, which allow of the transition of sugars and starches into alcoholic products, and also broadly indicates how those processes are carried out in practice.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Psychophysical Interaction.

A BRIEF note to remove a possible misunderstanding suggested by Prof. Minchin. He seems to think, or to imagine that others will think, that when speaking of the action of mind on matter I conceive of mind as a thing that can sustain a "reaction"; so that a stress might exist with matter at one end and mind at the other. Such an absurdity would indeed play havoc with the laws of mechanics; at any rate, I never entertained such a notion for a moment, whether for a guiding or for any other kind of force. If I lift a table it is quite certain that the weight of the table, *plus* its mass-acceleration, is transmitted through my boots to the floor: so far mechanics is supreme. But not even Prof. Minchin could calculate whether I shall lift the table or not, nor what I shall do with it when I have lifted it. I should obey every law of mechanics if I cast it on a bonfire; but I should have interfered with the course of nature, regarded as a mechanically determinate problem, even by only lifting it.

I want to understand the nature of this interference better; I have no other "anxiety" on the subject.

Incidentally I should like to transfer to your pages a most interesting and clearly-worded claim made by Sir W. T. Thiselton-Dyer in to-day's *Times*:—

"Directive power ... wipes out [meaning would wipe out if it were established] ... the whole position won for us by Darwin. It is no use mincing matters. Students of the Darwinian theory must be permitted to know the strength and weakness of their dialectic position. What that theory did was to complete a mechanical theory of the Universe by including in it the organic world." It is the last sentence to which I would direct attention.

Athenæum Club, May 15. OLIVER LODGE.

I AM not clear that it is wise to endeavour to aid Sir Oliver Lodge out of the pit he has, it seems to me, quite unnecessarily fallen into. But I will put a rope down to him, as it must be very uncomfortable down at the bottom.

Almost every mechanical problem leads by the application of ultimate mechanical principles to a differential equation. The solution of this equation involves a certain number of constants which may be infinitely many, but which we always find to be absolutely determined by the initial conditions. At first sight it seems difficult, without tacitly dropping a fundamental mechanical principle—such as that of momentum—to allow for "guidance" and "freewill" therein. But differential equations occasionally admit of *singular solutions*. We may follow up a particular solution, absolutely defined by the initial conditions, until we run onto the singular solution. After this we can stick to the singular solution or leave it again at any other contact with a particular solution, which will still satisfy the fundamental differential equation. Can "guidance" and freewill correspond to a shunt of this kind?

I am quite unaware of any differential equation in mechanics providing a good illustration of this suggestion. Still, we must get Sir Oliver up to the surface again, and this is the only rope by which I can conceive him ascending. κ.λ.π.ν.

"Red Rain" and the Dust Storm of February 22.

THE Marquess Camden recently sent me a sample of fine sand or dust collected from the roof of Bayham Abbey, Lamberhurst, shortly after the great dust storm of February 22, which I have caused to be examined. As the results appear to be of interest, especially in reference to Mr. Clayton's contribution to the *Proceedings* of the Chemical

Society, I should be glad if you could find space in NATURE for an account of them.

The dust consisted essentially of ferruginous sand, chalk, and silicates of alumina, alkalis, lime and magnesia, mixed with a certain quantity of organic matter and with an appreciable proportion of lead.

The last-named substance is probably due to the sample having been collected from a leaded roof. It may either have been scraped off during the taking of the sample, or, possibly, cut from the leads by the impact of sand particles driven against the roof by a high wind. Traces of tin and arsenic were also present in the sample; these were probably contained as impurities in the lead.

The detailed results of the analysis are as follows:—

(Substance dried at 100° C. before analysis.)

	Per cent.
Loss on heating to redness	11·28
Lead, calculated as oxide	3·31
Arsenic	0·01
Tin	Traces

After deducting the lead, tin and arsenic as being probably adventitious, the remainder of the sample is made up of the following constituents:—

	Per cent.
Silica	45·94
Alumina	18·35
Iron oxide	6·57
Lime	8·64
Magnesia	1·86
Alkalis { Sodium oxide	1·16
Alkalis { Potassium oxide	2·30
Carbonic acid	6·10
Water and organic matter	9·08
	100·00

The organic matter contained 2·19 per cent. of carbon and 0·16 per cent. of nitrogen, the two representing, probably, between 3 and 4 per cent. of organic constituents.

After being heated to redness, 33·30 per cent. of the sample was found to be soluble in hydrochloric acid, the dissolved portion including practically the whole of the lead, with the traces of tin and arsenic. Again deducting those elements, the dissolved constituents were as follows:—

	Per cent.
Silica	0·64
Alumina	11·20
Iron oxide	5·43
Lime	8·19
Magnesia	1·13
Alkalis	1·46
Carbonic acid	3·48
	31·53

Thus about one-third of the sample is dissolved by hydrochloric acid, including the greater part of the alumina, iron, lime and magnesia, but only a small fraction of the silica.

Dilute acetic acid readily dissolved out the greater part of the lime, with liberation of carbonic acid gas. Water alone dissolved practically nothing from the sample except minute traces of lime. These results show that most of the lime is present in the sample in the form of chalk.

One or two particles of metallic lead were detected in the sample, together with others partly oxidised and carbonated.

It has been surmised by Dr. Mill and others that the sand which accompanied the storm of February 22, and was observed to fall in a great number of places in this country as well as on the Continent, was originally derived from the African deserts.

It would be interesting in this connection to compare its characters with that of the dust, also presumably of African origin, which was observed to fall in the neighbourhood of Taormina, by Sir Arthur Rücker, and was made the subject of an interesting communication to NATURE by Prof. Judd about a year ago. T. E. THORPE.

Government Laboratories, London, W.C.

The Undistorted Cylindrical Wave.

THE receipt of a paper by Prof. H. Lamb, "On Wave Propagation in Two Dimensions" (*Proc.* Lond. Math. Soc., vol. xxxv. p. 141), stimulates me to publish now a condensation of a portion of a work which will not be further alluded to. I once believed that there could not be an undistorted cylindrical wave from a straight axis as source. But some years ago the late Prof. FitzGerald and I were discussing in what way a plane electromagnetic wave running along the upper side of a plane conducting plate, and coming to a straight edge, managed to turn round to the other side. Taking the wave as a very thin plane slab, one part of the theory is elementary. The slab wave itself goes right on unchanged. Now Prof. FitzGerald speculatively joined it on to the lower side of the plate by means of a semi-cylindrical slab wave. I maintained that this could not possibly work, be ause the cylindrical wave generated at the edge was a complete one, causing backward waves on both sides of the plate. Moreover, it was not a simple wave, for the disturbance filled the whole cylindrical space, instead of being condensed in a slab. It was in the course of examining this question that I arrived at something else, which I thought was quite a curiosity, namely, the undistorted cylindrical wave.

Maxwell's plane electromagnetic wave consists of perpendicularly crossed straight electric and magnetic forces, in the ratio given by $E = \mu v H$. Thinking of a thin slab only, it travels through the ether perpendicularly to itself at speed v, without any change in transit. I have shown that this may be generalised thus. Put any distribution of electrification in the slab, and arrange the displacement $\mathbf{D}$ in the proper two-dimensional way, as if the medium were non-permittive outside the slab. Then put in $\mathbf{H}$ orthogonally, according to the above mentioned rule, and the result is the generalised plane wave, provided the electrification moves with the wave. Otherwise, it will break up. Another way is to have the electrification upon fixed perfectly conducting cylinders arranged with their axes parallel to the direction of propagation.

Now the first kind of plane wave has no spherical analogue, obviously. But I have shown that the other kinds may be generalised spherically. Put equal amounts of positive and negative electrifications on a spherical surface arranged anyhow. Distribute the displacement in the proper way for a spherical sheet, as if constrained not to leave it. Then put in $\mathbf{H}$ orthogonally as above. The result constitutes an undistorted spherical electromagnetic wave, provided the electrification moves radially with the wave, and attenuates in density as its distance from the centre increases, in the proper way to suit $\mathbf{E}$ and $\mathbf{H}$. This attenuation does not count as distortion. Similarly, the other sort of generalised plane wave may be imitated spherically by having conical boundaries.

But when we examine the cylinder, there is apparently no possibility of having undistorted waves. For with a simple axial source it is known that if it be impulsive, the result is not a cylindrical impulse, but that the whole space up to the wave front is filled with the disturbance. It is easy to see the reason, for any point within the wave front is receiving at any moment disturbances from two points of the source on the axis, and there is no cancellation. And if the source be on a cylindrical surface itself, producing an inward and an outward wave, the whole space between the two wave fronts is filled with the disturbance.

How, then, is it possible to have an undistorted wave from a straight line source? By not arguing about it, but by showing that it can be done. The reason will then come out by itself. As the solution can be easily tested, it is only necessary to give the results here. Take plane coordinates r and θ. Let the magnetic force be perpendicular to the plane, of intensity H. Let Z be its time-integral, then

$$Z = \frac{\cos\frac{1}{2}\theta}{v r^{\frac{1}{2}}} f(vt - r), \qquad H = \frac{\cos\frac{1}{2}\theta}{r^{\frac{1}{2}}} f'(vt - r), \qquad (1)$$

expresses the magnetic field, f being an arbitrary function. Now the displacement $\mathbf{D}$ is the curl of $\mathbf{Z}$. So if E_1 is the radial component of $\mathbf{E}$, and E_2 the tangential component, in the direction of increasing θ, we have the electric field given by

$$E_1 = \frac{-\mu v \sin\frac{1}{2}\theta}{2r^{\frac{1}{2}}} f, \qquad E_2 = \frac{\mu v \cos\frac{1}{2}\theta}{r^{\frac{1}{2}}} f' + \frac{\mu v \cos\frac{1}{2}\theta}{2r^{\frac{1}{2}}} f. \qquad (2)$$

The attenuation factor $r^{-\frac{1}{2}}$ in (1) does not count as distortion.

The wave may go either way, and various cases can be elaborated. If the wave is outward, the axis ($r=0$) is the source. The plane $\theta=0$ is a perfect electric conductor. The electrification is of the same sign on its two sides. Other details may be got from the formulæ.

I give an example to show the not very obvious electrical meaning. Let the infinite plane conductor with the straight edge be one pole of a condenser, and a straight wire placed parallel to the edge, and close to it, be the other pole. Join them by a battery, charging the plate and the wire. Bring the wire right up to the edge, and reduce its magnitude to a mere line. (This is to be done in order to attain the ideal simplicity of the formulæ.) Take away the battery. Then the electric field is given by

$$cv\mathrm{E}_1 = -\frac{\sin\frac{1}{2}\theta}{2r^{\frac{1}{2}}}f_0, \qquad cv\mathrm{E}_2 = \frac{\cos\frac{1}{2}\theta}{2r^{\frac{1}{2}}}f_0, \tag{3}$$

where f_0 is a constant and c is the permittivity.

Finally, discharge the condenser by contact between edge and wire. Then the result at time t later is that outside the cylinder of radius $r=vt$ the above field (3) persists, whilst inside the cylinder there is no **E** or **H**. An electromagnetic wave separates these regions. It started from the axis at the moment of contact, and as it expands swallows up the whole energy of the field, and carries it to infinity. Similarly, as regards the charging of the plate, only the "battery" should, to have the same formulæ, be an impressed force acting at the axis, between the edge and the wire. At time t after contact, the electric field is established fully within the cylinder $r=vt$. On its boundary is the impulsive wave which is laying down the remainder. It also, if the contact be instantaneous, wastes an equal amount of energy at infinity.

Similarly, by varying the impressed voltage anyhow with the time, the emission of an arbitrary wave of **H** results. With a real plate and real wire, the main features would no doubt be the same. The use of the line wire introduces infinite voltage.

What somewhat disguises the electromagnetics is the existence of the steady electric force, or parts thereof, along with the electromagnetic **E** and **H**, particularly when f is arbitrary. There is a similar complication in the spherical wave when the total electrification in any thin shell is not zero. There is then an auxiliary internal or external electric force to make continuity.

We cannot have an undistorted wave from a simple line source. But in the example the apparent line source will be found to be a doublet. For the curl of **e** (impressed force) is the source of the wave. It is double, positive on one side, negative on the other.

Solutions of the type

$$\mathrm{H} = \Sigma\frac{\mathrm{A}r^{n}\cos(n\theta+a)}{(v^2t^2-r^2)^{n+\frac{1}{2}}} \tag{4}$$

or the same with r and vt interchanged in the denominator, are not distortionless, save for the solitary term in which $n=-\frac{1}{2}$. The above distortionless cylindrical wave (1) is unique. Prove by the characteristic.

April 29. OLIVER HEAVISIDE.

Seismometry and Geite.

UNDER the above heading Prof. J. Milne contributed an interesting article to NATURE of April 9, p. 538, on which I wish to offer some remarks. Prof. Milne seems hardly to realise the significance of the enormous pressures to which the earth's deep-seated material is presumably exposed. One of his objections to the hypothesis of an iron core seems to be that the wave velocities for an infinite isotropic medium of the density and elasticity of iron do not accord with the velocities of earthquake waves. This objection, however, is not conclusive. In an infinite isotropic medium there are *two* purely elastic wave velocities, v_1 and v_2, given by the equations

$$v_1 = \sqrt{(m+n)/\rho}, \quad v_2 = \sqrt{n/\rho},$$

where ρ is the density, m and n Thomson and Tait's two elastic constants. On the ordinary theory, n/m may possess any value consistent with Poisson's ratio γ, or $(m-n)/2m$, lying between 0 and 0·5. Six years ago I showed (*Phil. Mag.*, March, 1897, p. 199) that observed seismic wave velocities can be accounted for by elastic waves without postulating any abnormal value for Young's modulus—the modulus to which Prof. Milne repeatedly refers. For instance, we get values of 12·5 and 2·5 kilometres per second respectively for v_1 and v_2 in a medium of density 5·5 with a Young's modulus of only 10^9 grammes weight per sq. cm., if we suppose $n/m=1/24$, or $\gamma=0{\cdot}48$ approximately; and the same results follow if we increase density and elastic constants in the same proportion.

In iron, as we know it, γ, of course, is not 0·48, but more nearly 0·25. A material, however, which under low pressures has $\gamma=0{\cdot}25$, *may*, after prolonged exposure to enormous pressures, behave as an elastic medium with γ very nearly 0·5. In fact, if the deep-seated material acts as an elastic medium, the only consistent way yet pointed out for its doing so is by its behaving as if γ were very near the limiting value answering to incompressibility. Neither of the elastic wave velocities, it should be noticed, has anything directly to do with Young's modulus, a point which cannot be too clearly emphasised. Another consideration is the possibly appreciable influence of gravity on the wave velocities.

Coming now to the question of the behaviour of magnetographs at times of seismic disturbance, there must undoubtedly be magnetic disturbances occasioned by earthquakes in more than one way. When a violent earthquake occurs where magnetic material abounds, there may be a vast movement of magnetised matter; there may be a great change in the stresses throughout adjacent magnetic material; and there may be a great change of local temperature. Any one of these causes will give rise to a magnetic disturbance which should be practically simultaneous all over the world, and should *precede* any seismic movement at distant stations. It should also diminish very rapidly as the distance from the earthquake origin increases.

Again, as the seismic waves travel out from their source they must cross volumes of magnetic matter, and the mechanical effect on any such volume must necessarily produce changes in its magnetic field. Owing to the finite velocity of seismic waves, the displacements and stresses simultaneously existent in different parts of any large magnetic volume must be in all kinds of phases, leading to considerable interference between the magnetic disturbances to which the different parts give rise at any considerable distance. Thus the most plausible explanation of why a magnetic disturbance of some prominence—if real—should appear at one observatory, but not at another only 100 miles off, is certainly the existence of magnetic material close to the former. Supposing that such local material exists, the magnetic phenomena may be expected to vary according to the direction in which the earthquake wave is travelling.

One of the chief difficulties in reaching definite conclusions is the contracted time scale usual in magnetograms. If the true seismic and the apparent magnetic disturbances occur within a few seconds of one another, it is usually practically impossible to say which is the earlier. To see the full force of this, one must remember that a by no means improbable explanation of why apparent magnetic disturbances accompany earthquakes at one station, but not at another, is that the magnets at the former, owing to pattern or site, may be much more sensitive *seismographs* than those at the latter.

Again, it must be remembered that whilst the so-called "large waves"—rather an unfortunate term—produce in general a much greater effect on a horizontal pendulum than do the "preliminary tremors," it by no means follows that the same will be true of either the true magnetic or the purely mechanical effects on a magnet. Much may depend on the method of support and the time of swing.

The passage of the "preliminary tremors" and "large waves" due to an earthquake often occupies several hours, and during this interval several true independent magnetic movements are not at all unlikely to present themselves, even at times of general magnetic calm.

For all these reasons a careful intercomparison is wanted of magnetic and seismic records from a variety of stations. Something might be done by running magnetographs for some time in a district where a local magnetic disturbance

is known to exist, and contrasting the results with those obtained elsewhere with the same instruments.

Prof. Milne mentions Kew and Greenwich as representatives of stations where magnetic and gravitational anomalies do not exist, but, as a matter of fact, Rücker and Thorpe's magnetic survey does show a small magnetic anomaly in the Thames Valley, and certain foreign observers have also inferred a gravitational anomaly.

As to Prof. Milne's special term "gēite" for material in the earth's interior, I must confess that the application of a new word to the unknown material of a problematical core seems to me more likely to hinder than assist. Such special terms constitute an additional obstacle in the way of those who are not specialists. Also existing terms, such as nucleus and core on the one hand, and layer or crust on the other, seem not inadequate, the context showing whether it is the material that is immediately in view.

I have had repeated occasion to deal with elastic problems involving a core and a layer or layers. In fact, the very "earth" for which Prof. Milne expresses a preference, consisting of a layer of about 1/20 of the earth's radius in thickness with a density of average surface rock, and a core of specific gravity approaching 6, is one which I selected some years ago for the purpose of investigating luni-solar tidal action (*Cambridge Phil. Trans.*, vol. xvi. p. 151). Thus I do not speak without experience.

A final point to be remembered is that, according to the investigations of Gauss and others, the earth itself is a magnet of considerable moment. Any theory which claims even provisional acceptance may be expected to give a plausible explanation of this fact, and of the secular change observed in terrestrial magnetism. C. CHREE.

Photograph of Oscillatory Electric Spark.

THE enclosed photograph of an oscillatory electric spark, like most of those which I have taken, differs in some respects, so far as I have seen, from those which have been recorded by other experimenters. It was obtained by the discharge of 22 square feet of coated surface through

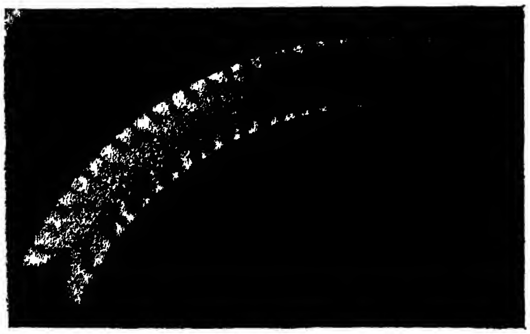

FIG. 1.—Oscillatory electric spark.

¼ mile of coiled wire, the electrodes being of magnesium. The picture was focused on a circular plate fixed on the end of an electric motor, so as to revolve in its own plane. The number of double oscillations was about 3000 per second. C. J. WATSON.

Bottville Road, Acocks Green, Birmingham.

Our Rainfall in Relation to Brückner's Cycle.

IN the instructive paper on solar and meteorological changes in NATURE (May 7), I observe that Dr. Lockyer suggests 1913 as probably about the centre of the next wet period. A consideration of barometric changes appears to lead to a similar result, and I may be permitted to recall a letter sent you in 1898 (NATURE, December 22, p. 175), in which, discussing with such data the question, "Where do we stand in Brückner's cycle?" I mentioned 1911 as probably near that centre. Such estimates must, of course, be regarded as merely approximate, and open to revision.

This important cycle of Brückner's was lately discussed in a number of letters to the *Times*, and it is satisfactory to see that more adequate attention is now, though tardily, being given it.

Is it not objectionable to treat the British Isles as a whole, since, on Brückner's theory, the western portion shows opposite variation to the eastern?

There is a method of curve-making which seems to be little used by meteorologists, but which is, I think, to be recommended. A series of annual rainfall figures (say) is first translated into a series of plus and minus values (related to the average), and this series is then added algebraically step by step, *e.g.*

$$+9{\cdot}3-1{\cdot}4+0{\cdot}6+0{\cdot}9-1{\cdot}6+1{\cdot}3, \text{ \&c.}$$
$$+7{\cdot}9+8{\cdot}5+9{\cdot}4+7{\cdot}8+9{\cdot}1, \text{ \&c.}$$

This second series is then thrown into curve form. The process is analogous to paying in money to a bank, and drawing money out, and the point reached by the curve at any given time indicates the balance.

Each upward (annual) extension in such a curve represents a wet year, and each downward extension a dry year, and the degree of wetness or dryness is also indicated.

A large comparison of such curves for European and other stations would, I think, throw a good deal of light on the Brückner theory. ALEX. B. MACDOWALL.

The Propagation of Phthisis.

IN a work called "Opera nuova intitulata il Perche, utilissima ad intendere le cagioni de molte cose, &c.," published in Venice in 1520, the following passage occurs:—"Dal sputo del Tisico o da la sua boca viene fuora un vapore fetido e acuto che entra poi per la boca de colui che conversa con quello e corrode simelmente il pulmone de esso e in questo modo genera tisica."

Substitute for *vapore* "material particles," and we have the modern conception of the mode of propagating consumption. This anticipation of modern science seems worthy of note. EDMUND MCCLURE.

TANGANYIKA.[1]

THE title of this work is perhaps somewhat misleading. The reader who expects the book to contain only discussions of speculative questions will be agreeably surprised by finding that the positive contributions made in it to our knowledge of the geology, botany and zoology of Central East Africa are of the most extensive and valuable character. The two expeditions which the author undertook in 1896 and 1899 to Lake Tanganyika and the surrounding districts, following upon the researches of earlier travellers, have thrown a flood of light upon both the geological structure and the fauna and flora of this part of the world, while they have incidentally suggested a number of difficult problems of no small interest alike to the geologist and the biologist.

The surveys of Mr. Moore and of Mr. Malcolm Ferguson, the geologist who accompanied him, have been of value in rectifying and making noteworthy additions to the maps of the area visited. The geographer will find references to a number of new mountain peaks, the heights of many of which are given, with the determination of the heights above sea-level and the depths of many of the lakes, in several of which numerous soundings and dredgings were made.

One of the most valuable results of Mr. Moore's explorations is the confirmation he is able to supply to the conclusions of Mr. Scott Elliot that there exists in East Central Africa a great mountain chain running north and south, and rising at many points, even in this Equatorial region, above the limits of perpetual snow. The height of the snow-line is fixed by Mr.

[1] "The Tanganyika Problem; an Account of the Researches undertaken Concerning the Existence of Marine Animals in Central Africa." By J. E. S. Moore, F.R.G.S., author of "To the Mountains of the Moon." Pp. xxiii + 371; with 7 maps and 140 illustrations. (London: Hurst and Blackett, Ltd., 1903.)

Moore at 13,500 feet, and some of the peaks he thinks may attain a height of 16,500 feet, while Sir Harry Johnston believes that 20,000 feet is a probable minimum of the height of some of them. This great mountain chain, giving rise in some parts of its course to numerous glaciers—the "Mountains of the Moon" of the ancients—Mr. Moore proposes to call "the Great Central African Chain." It extends from the mountains of Abyssinia in the north to the Drakensberg in South Africa, though in some places, as in the neighbourhood of Tanganyika and the Albert Edward Nyanza, it is a broad ridge, the culmination of long eastern and western slopes, rather than a conspicuous chain; so that, viewed from either side, it has little resemblance to a mountain range, even when its summits rise ten or twelve thousand feet above the sea-level.

Mr. Moore discusses the geological structure of this great mountain chain, giving a number of valuable geological sections across it at various points. The origin of the range, he believes, must be assigned to lateral compression, the celebrated "rift-valleys" being regarded by him as subordinate features resulting from the orographic movements in the earth's crust. Although volcanic action has only played a subordinate part in the formation of the great chain itself, in the greater portion of its course, yet in the district lying to the north of Tanganyika, which was carefully explored by our author, we have the still active volcanic district of the Mfumbiro Mountains, a chain of volcanoes running east and west; the highest of these, Karisimbi, is often snow-capped, and has a height of 14,000 feet. Mr. Moore shows that the structure of the great longitudinal valley in which Tanganyika lies has been profoundly modified by the ejection of the materials forming the Mfumbiro chain. The surface of Lake Kivu, to the north of Tanganyika, is 4841 feet above sea-level, while Albert Edward Nyanza, still further north, lies 2000 feet lower, and Tanganyika has a height of 2700 feet. The author points out that previously to the formation of the Mfumbiro volcanic cones, the waters of Lake Kivu must have drained northwards into the Albert Edward Nyanza, and not, as now, into Lake Tanganyika, by the Russisi River. Numerous other volcanic cones occur in the district, generally at the bottom of the rift-valleys. The waters of Lake Kivu contain such a large amount of salts that the pebbles and reeds on the shores become encrusted with a calcareous deposit, which analysis shows to contain 12·66 per cent. of magnesium to 28·65 of calcium. The waters of Lake Kivu, which is sometimes more than 100 fathoms deep, have been analysed and found to contain a very large proportion of magnesium carbonate.

The geological formations met with in the expeditions, the distribution of which in the neighbourhood of the several lakes is shown upon sketch-maps, are as follows, beginning with the oldest:—

(1) Old crystalline rocks—granite, gneisses, schists, quartzite, &c.

(2) Great thickness of unfossiliferous sandstones and shales.

(3) "Drummond's beds," a series of sandstones and shales of about the age of the Trias.

(4) Recent lacustrine strata.

Unfortunately, no satisfactory evidence has yet been adduced as to whether the stratified rocks (2) and (3) can, either or both of them, be regarded as of *marine* origin, and some of the unsolved problems of African geology must await full solution until this determination has been made. At present we have no proof that the stratified masses of the older formation are not, like those of the younger, of lacustrine or fluviatile origin.

Around some of the great Central African lakes there are found extensive alluvial deposits containing the shells of species of Mollusca, which still live in the waters of the adjoining lake. These, with the numerous raised beaches, show that some of the lakes had formerly a much greater extent than at present. It is upon these old alluvial deposits that the celebrated "Park-lands," so well described and so convincingly explained by Mr. Moore, are found. Among the botanical results of the two Tanganyika expeditions, not the least valuable are the investigation of these curious features that have attracted so much attention from all travellers in the district. Mr. Moore shows how the springing up of scattered individuals of the hardy euphorbias has afforded a shade under which plants less able to withstand the burning heat of the sun have grown up and gradually extended outwards. Of course, in the end, these outward spreading patches of vegetation must coalesce and form a tangled forest growth, such as occurs in other parts of Central Africa. Mr. Moore ingeniously argues that the amount of development towards this forest growth may be utilised as a means of determining the geological age of the alluvial flats upon which they are found.

It is on the zoological results of these expeditions, however, that the author of the work before us must be especially congratulated. The addition of nearly 200 species of animals to the fauna of the district is the least important of his achievements, though it shows how assiduous and successful must have been his work as a collector. But Mr. Moore is far more than a collector. By careful observations and experiments carried on during his residence among the lakes, by his studies of living animals in their peculiar environment, and by his work in the laboratory upon the specimens he has brought home, he has made the most substantial additions to zoological science.

On questions of distribution the researches of Mr. Moore have a very important bearing. The discovery by Speke and the missionaries of marine types of mollusca in the waters of Tanganyika, followed as it was by Boehm's discovery of a medusa in the same fresh waters, made it a question of first importance to determine whether the same phenomena were exhibited in any other of the African lakes. To this question Mr. Moore has afforded a complete answer. He has himself examined the faunas of lakes Shirwa, Nyassa, Kela, Tanganyika, Kivu, the Albert Edward Nyanza, the Albert Nyanza, the Victoria Nyanza, and Nivasha. The faunas of four or five more lakes are less perfectly known from the work of other travellers, and it is now certain that the peculiar "halolimnic fauna," as Mr. Moore calls it, is confined to Tanganyika, all the other neighbouring lakes containing only the ordinary types of fresh-water mollusca and fish that occur in similar situations all over the globe. The account given of the distribution of these forms by Mr. Moore, especially in the salt lake of Shirwa, will prove of interest both to zoologists and to geologists.

The fish-fauna of Tanganyika consists of eighty-seven species, of which no less than seventy-four are new to science, and have been described and figured by Mr. Boulenger. The medusa (*Limnocnida tanganyicae*) of Tanganyika has been described from spirit specimens by Mr. Robert Günther, of Oxford; but Mr. Moore has been able, during his residence at the lake, to make drawings of the living animal, to work out its development, and to add much to our knowledge of its habits. We reproduce his drawings of this curious organism, which varies in size from a shilling to a two-shilling piece.

The complete study of the anatomy of the "halolimnic" gasteropods, which so closely resemble marine forms of the Jurassic period, has been carried out by

Mr. Moore and fellow-workers in the Royal College of Science, and a curious form of polyzoan, with some prawns and sponges, have been added to the fauna with marine affinities that have made Tanganyika so interesting to naturalists.

Want of space forbids our entering on a discussion of the theoretical questions dealt with in the work

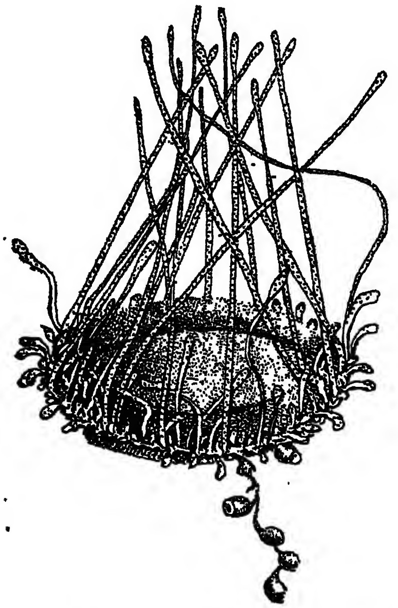

Fig. 1.—Living asexual adult of the Tanganyika medusa, enlarged about one-third. To the right is seen a string of buds becoming detached.

before us. On many of these the last word has not been said, and some of the speculations put forward by the author can be regarded as having only the value of ingenious suggestions. In dealing with so large a mass of new and varied material, the author may have been led in places to express hasty judgments,

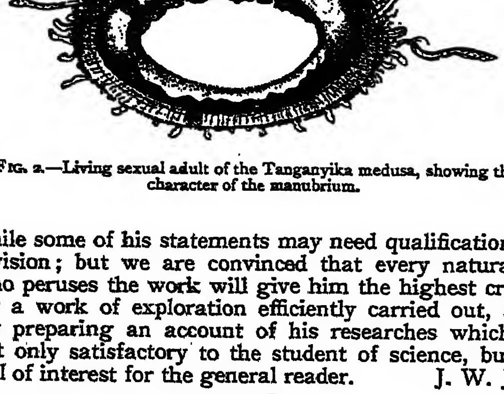

Fig. 2.—Living sexual adult of the Tanganyika medusa, showing the character of the manubrium.

while some of his statements may need qualification or revision; but we are convinced that every naturalist who peruses the work will give him the highest credit for a work of exploration efficiently carried out, and for preparing an account of his researches which is not only satisfactory to the student of science, but is full of interest for the general reader. J. W. J.

ENLARGEMENT OF THE KEW HERBARIUM.

Sir William J. Hooker, the first director of Kew Gardens, as a public establishment, was really the founder of the herbarium at Kew, for before any bequests or gifts were made, his extensive private collection of dried plants and books was, by arrangement with the Government, used for the purposes of the gardens, and accessible to botanists of all countries. When Sir William took up his appointment in 1841, there was neither specimen nor book the property of the garden, and his herbarium and library were first deposited in his own residence at West Park. In 1853 his herbarium and a portion of his library were lodged in the original portion of the present block of buildings, and he received a small annual grant from Government for assistance and maintenance, on the condition that the plants and books were free to other botanists. The same year Miss Bromfield presented the herbarium and library collected by her deceased brother, W. Arnold Bromfield, the author of the "Flora Vectensis," which was edited after his death by Sir Joseph Hooker.

This gift, though not so extensive as some subsequent ones, was very valuable, both in plants and books, the latter including a number of excellent copies of the best editions of many of the early authors, or "old masters." The following year, 1854, Mr. George Bentham presented his very rich herbarium and library to the nation, on the condition that they should be deposited at Kew, and so housed and arranged as to be accessible to himself and other botanists. I may add, parenthetically, that Bentham continued his botanical work at Kew, almost uninterruptedly, for thirty years, the end of which saw the completion of the "Genera Plantarum" of Bentham and Hooker, a work which has not yet been replaced by an equally concise and useful synopsis of a uniform character. Sir William Hooker died in 1865, and in 1866 the Government purchased his herbarium and library, so far as they were not already represented in the national collection at Kew. This purchase included museum specimens, drawings, manuscripts, portraits of botanists, and Sir William's botanical correspondence, covering a period of sixty years. As is well known to the older generations, Sir Joseph Hooker succeeded his father in the directorship, and he in turn was succeeded by his son-in-law, Sir William Thiselton-Dyer, the present director.

Under these successive directors, due greatly to their activity and zeal, the collections of plants and books have continued to increase with great rapidity, partly from increasing Government grants, and partly from private munificence. Among the latter the collections specially deserving mention are:—A. Cunningham's Australasian; Burchell's St. Helena, S. African and S. American; Borrer's British; H. C. Watson's British; Miss Griffith's Algæ; Wight and Rottler's Indian; Boott's Carices; J. Gay's general, presented by Sir Joseph Hooker; Ball's general herbarium and botanical library; Carey's N. American; and quite recently Dr. Alexander Prior's general herbarium, received through Sir Prior Goldney.

All these important gifts consist mainly of named and mounted specimens. Smaller donations number many hundreds. The enormous Indian collections of Hooker and Thomson reached Kew in 1851. They were estimated at 8000 species, and the specimens were so numerous that no less than sixty sets were given away to other botanists and botanical establishments. The distribution of these specimens, and seven wagon-loads of specimens (chiefly of Griffith, Helfer and Falconer's collecting) received from the India House in 1858, was not completed until 1863.

The rapid growth of the herbarium and library neces-

sitated enlargement of the building about twenty-five years ago, when a large hall was added. This is a quadrangular structure eighty-six feet by forty-three feet, with a ground floor and two galleries connected by two spiral staircases, and lighted by forty-eight windows. A second hall of the same dimensions has just been completed, and will soon be occupied. It is connected with the old hall on each floor by a corridor fifty-six feet long, and the floors and roof are of concrete, and it is intended to replace those of the old hall with the same material at once. It is estimated that the entire collection comprises considerably more than 2,000,000 specimens, attached to 1,300,000 sheets.

With the exception of Carey's North American herbarium, Lindley's orchids, and Borrer and Watson's British herbaria, the plants from all parts of the world are arranged in one series, the genera according to Bentham and Hooker's "Genera Plantarum," and the species geographically. It is unnecessary to enlarge on the value of a herbarium containing the types of all the colonial floras and other works issued from Kew—it is known to all botanists. The library, which the present director has made his special care, is one of the richest, even if not the richest, in existence, and is in admirable condition. It comprises upwards of 20,000 volumes, besides about 10,000 pamphlets. The Government published a catalogue of the books in 1899, and annual supplements since. There is also a separate collection of about 100,000 published figures and original drawings of plants.

W. Botting Hemsley.

THE SOUTH AFRICAN ASSOCIATION.

The inauguration of the South African Association for the Advancement of Science took place at Cape Town on April 27. The *Cape Times*, to which we are indebted for the details of the proceedings, describes the successful gathering as a British Association meeting in miniature. The new Association enters upon its career with a membership of seven hundred persons from many parts of South Africa.

The main objects of the organisation are the same as those of the parent body. As defined in the Constitution, they are "to give a stronger impulse and a systematic direction to scientific inquiry; to promote the intercourse of societies and individuals interested in science in different parts of South Africa; to obtain a more general attention to the objects of pure and applied science, and the removal of any disadvantages of a public kind which may impede its progress."

The presidential address was delivered by Sir David Gill, K.C.B., the Astronomer Royal for South Africa, who explained the nature of the work which it was hoped the new Association would accomplish. During the course of his able address Sir David Gill announced that Lord Kelvin had written that, although in 1905 he will be eighty-one years of age, he intends, if he is as well then as he is now, to accompany the British Association on the visit to South Africa.

The work of the sections began on the second day of the meeting. The presidential addresses in the various sections were delivered by the following men of science:—

Section A.—Astronomy, Chemistry, Mathematics, Meteorology, and Physics, by Prof. P. D. Hahn; Section B.—Anthropology, Ethnology, Bacteriology, Botany, Geography, Geology, Mineralogy, and Zoology, by Dr. R. Marloth; and Section C.—Archæology, Education, Mental Science, Philology, Political Economy, Sociology, and Statistics, by Dr. Thomas Muir, C.M.G., F.R.S., Director of Education for Cape Colony.

Among the papers read during the course of the meetings the following deserve mention. In Section A, on ferments causing "casse" in wine, by Mr. Raymond Dubois; meteorology in South Africa: a retrospect and prospect, by Mr. C. M. Stewart; close binary systems, by Dr. Alex. W. Roberts; determination of mean temperature, &c., from observations made at second-order stations on the Table Land, by Mr. J. R. Sutton; some recent work on the discharge of electricity from heated bodies, by Prof. J. C. Beattie.

In Section B, (1) on the occurrence of an epidemic among the domesticated animals in Mauritius in which Trypanosomata were found in the blood; (2) note on the co-relation of several diseases occurring among animals in South Africa; (3) on the production of a malarial form of South African horse sickness, by Dr. Alex. Edington; the minerals of some South African granites, by Mr. F. P. Mennell; on the classification of the Theriodonts and their allies, by Dr. R. Broom; (1) some morphological and biological observations on the genus Anacampseros; (2) on some stone implements in the Albany Museum, by Dr. S. Schonland.

In Section C, some aspects of South African forestry, by Mr. D. E. Hutchins; dry crushing of ore preparatory to the extraction of gold, by Mr. Franklin White; sewage disposal in Cape Colony, by Mr. J. Edward Fitt.

In Section D, the library system of South Africa in comparison with those of England and America, by Mr. Bertram L. Dyer; iteration as a factor in language, by Prof. W. Ritchie; common sense and examination, by Mr. P. A. Barnett; Cape Dutch, by Prof. W. S. Logeman; how we get knowledge through our senses, by Rev. Dr. F. C. Kolbe.

The example set by the British Association of arranging for receptions and other social functions to lighten the intellectual fare provided was followed at Cape Town, and the excursions, conversazioni, &c., were well attended and much appreciated.

THE ROYAL SOCIETY CONVERSAZIONE.

The conversazione held at the Royal Society on Friday last was attended by a large and distinguished company, among the visitors being H.R.H. the Prince of Wales and H.S.H. the Duke of Teck. There were numerous exhibits illustrating progress in various branches of science, several of them being of great interest. Following our usual course, we abridge the particulars given in the descriptive catalogue as to the character and purpose of the objects on view.

Sir William Crookes, F.R.S., exhibited objects illustrating certain properties of the emanations of radium. If a solid piece of radium nitrate is brought near a blende screen, and the surface examined with a pocket lens magnifying about 20 diameters, scintillating spots are seen to be sparsely scattered over the surface. On bringing the radium nearer the screen the scintillations become more numerous and brighter, until when close together the flashes follow each other so quickly that the surface looks like a turbulent luminous sea. A convenient way to show these scintillations is to fit the blende screen at the end of a brass tube with a speck of radium salt in front of it and about a millimetre off, and to have a lens at the other end. Focusing, which must be accurately effected to see the best effects, is done by drawing the lens tube in or out. It is proposed to call this little instrument the "Spinthariscope."

Specimens of brittle gold and photographs illustrating their microstructure were shown by Dr. T. K. Rose. Gold of the British imperial standard, containing 91·6 per cent. of gold and 8·3 per cent. of copper, is made brittle and unfit for coinage by the presence of minute traces of certain impurities such as tellurium, lead, bismuth, &c. Similar or even considerably greater quantities of these elements, excepting bismuth, do not affect the ductility of fine gold. The deleterious effects of the impurities are removed by the presence of oxide of copper dissolved in the metal. The changes in the quality of coinage bars are accompanied by profound changes in the microstructure of the metal.

Dr. Morris W. Travers exhibited hydrogen thermometers for measuring low temperatures. The thermometers are of the constant-volume type, and are intended for the

measurement of temperatures between 0° and −253° C. One is graduated directly in degrees on the hydrogen scale, and can be employed for the direct measurement of low temperatures to within one degree. The other is intended for more accurate measurements.

A new coherer, as applied to wireless telegraphy, was shown by Sir Oliver Lodge, F.R.S., and Dr. Alexander Muirhead. A steel wheel rotates so that its edge touches a pool of mercury through a film of oil. (See *Proc.* Roy. Soc., March.) This is the coherer, and its decoherence is automatic. A fraction of a volt is used in the detecting circuit, which works a siphon recorder as the receiving instrument. The sending part of a station, including an automatic transmitter and a "buzzer" for carving a steady current into intermittencies, was also shown.

Incandescent oil burners were exhibited by Mr. T. Matthews. These burners have been designed by the exhibitor primarily for use in the Trinity House Lighthouse Service. The intensity of the single mantle burner for flashing lights is 1100 candles, and the consumption of oil one pint per hour; the intensity of the triple mantle burner for fixed and occulting lights is 2700 candles, and the consumption of oil three pints per hour, the flashing point of the oil being in each case from 145° to 160° Fahrenheit (close test).

Experiments on controlling and regulating spark discharges, shown by Mr. Alfred Williams, illustrate how the use of a shunt, or of a point and shunt, or of plates of high resistance, so influence the field in a spark gap that the discharges are made more regular and placed more under control for therapeutic and wireless telegraphy purposes.

The "Elasmometer," a new form of interference apparatus for the determination of the elasticity of solid substances, was exhibited by Mr. A. E. Tutton, F.R.S. The apparatus is designed to measure the amount of bending suffered by a thin plate of the substance investigated, when supported near its ends against a pair of platinum-iridium knife-edges, under a weight applied at its centre.

Prof. A. G. Greenhill, F.R.S., showed a gyroscopic pendulum, for lecture experiment. A bicycle wheel is suspended by a prolongation of its axis from a universal joint, formed with a hub and its ball-bearings. The wheel is rotated by a stick inserted in the spokes, and projected to illustrate the variety of gyroscopic motion.

Dr. W. Ramsden demonstrated by experiments and illustrated by photomicrographs and specimens, the presence and spontaneous formation of solid membranes upon the free surfaces of certain solutions. He also showed that solid membranes are present on certain bubbles.

Aërial photographs were shown by the Rev. John M. Bacon. Among the pictures was one showing the sea bottom at a depth of ten fathoms photographed from an altitude of 600 feet.

The physical sciences were also represented by the following objects and experiments:—A series of photographs and objects relating to Dr. William Gilbert, of Colchester (1544–1603), author of the treatise "De Magnete," Prof. Silvanus P. Thompson, F.R.S.; a direct vision spectroscope of one kind of glass, and of minimum deviation for any ray in the centre of the field of view, Mr. T. H. Blakesley (see p. 71); apparatus for the detection and estimation of minute quantities of arsenic in beer and brewing materials, as recommended by a Departmental Committee of the Board of Inland Revenue, Prof. T. E. Thorpe, C.B., For.Sec.R.S.; ephelkystika, or tractate curves, and machine for drawing them, Col. Hippisley, C.B., R.E.; (1) gravimetric recording hygrometer, (2) an electrical dewpoint hygrometer, Prof. F. T. Trouton, F.R.S.; Callendar's compensated barometer, Mr. N. Eumorfopoulos; light mirrors, suitable for galvanometers (see p. 72), Mr. W. Watson, F.R.S.; micrometer for measuring screws, made for the British Association Screw Gauge Committee, the Cambridge Scientific Instrument Company; photographs of dust deposits, Dr. W. J. Russell, F.R.S.; examples of Lippmann's process of photography in colours, Mr. Edwin Edser and Mr. Edgar Senior; an experiment illustrating the conductivity imparted to a vacuum by hot carbon, Mr. O. W. Richardson; a high pressure spark-gap used in connection with an inductor of the Tesla type, and also in connection with a radiator of Hertzian waves, Rev. F. J. Jervis-Smith, F.R.S.; diagrams illustrating the order and origin of the musical scales, Mr. Joseph Goold.

An artificial horizon attachment to sextants, exhibited by Commander Campbell Hepworth, C.B., consists essentially of a contact maker, operated by a plummet mounted on a sextant, and connected with a galvanic battery. It is so adjusted as to close the circuit and ring a bell when a slit or line on the horizon glass is in alignment with the eye of the observer and the sensible horizon. Observations for latitude and longitude at sea are rendered impossible when the natural horizon is obscured by fog or mist, although sun, moon, or stars may be shining clearly; but with the aid of this instrument the observer may obtain the true altitude of a heavenly body within five minutes of arc.

The Solar Physics Observatory, South Kensington, exhibited (1) photographic comparison of the arc spectra of various samples of dust; (2) curves, illustrating the long period solar and meteorological (rainfall) variations of about thirty-five years; (3) photographs of new curved slit by Hilger. This slit is used at the focus of the second objective of the photo-spectro-heliograph, and is intended for the isolation of the K (calcium) line in the solar spectrum, Nos. 3 *a* and *b*.

The use of a colour screen in photographing bright stars was illustrated by the Cambridge Observatory. By the use of a yellow spot on a worked glass screen in contact with the sensitive plate, the image of a bright star can be reduced to equality with the images of the comparison stars. It thus becomes possible to apply photography to the determination of the parallaxes of bright stars, which have been dealt with hitherto almost entirely by the heliometer.

The chromospheric spectrum near the South Pole of the Sun was shown by Mr. J. Evershed. Nebular spectra of Nova Persei from May 3, 1901, to January 14, 1902, with previous spectra for comparison, were illustrated by Mr. Frank McClean, F.R.S. Other exhibits were:—(1) collimating gun sight for day and night; (2) optical sight for guns and rifles; (3) spherometer of great delicacy, by Dr. A. A. Common, F.R.S.

Methods of disintegrating cells and microorganisms, and of obtaining their intracellular constituents, were shown by Dr. A. Macfadyen and Mr. S. Rowland. In the first method the cells are disintegrated by the violent impact of sand particles in the apparatus exhibited. In the second method the use of extraneous disintegrating material is dispensed with, the cells or organisms being disintegrated when in a frozen condition. In the apparatus exhibited the necessary cold and brittleness are secured by the use of liquid air.

Dr. Leonard Rogers exhibited five specimens of Hydrophidæ (poisonous sea snakes). These snakes swarm round the coasts of India and in other tropical seas, and cause some loss of life among fishermen. Their poison has recently been found to be more powerful than that of any other snakes.

Miss E. R. Saunders illustrated interesting cases of structural atavism resulting from cross-breeding. Experiments (Report Evolution Committee, 1902) with stocks suggested that when glabrous plants of dissimilar colours are crossed together, the offspring might be hoary. Actual trials have proved this to be true. When glabrous cream or white are crossed with each other, or with glabrous plants of other colours, the offspring are all hoary; but when colours other than white or cream are crossed together, the offspring are all glabrous.

Fossils in Cambrian quartzite were shown by Prof. J. Norman Collie, F.R.S. These fossils were found on the surface of a glacier in Desolation Valley (near Laggan Railway Station), Canadian Rocky Mountains.

Dr. Henry Woodward, F.R.S., exhibited two photographs of *Tetrabelodon* (*Mastodon*) *angustidens*, Cuvier, from the Miocene of Sansan, France, taken from the skeleton in the Museum of Natural History, Paris. This primitive form of Mastodon still retains two pairs of functional incisor teeth (tusks), one pair in the upper and one pair in the lower jaw, the upper ones being directed *downwards*. In modern elephants only one pair (the upper) incisors are present, and these are usually curved upwards. (See Dr. C. W. Andrews's paper, *Proc.* Roy. Soc., No. 474.)

The Royal Geographical Society had on view (1) hypso-

metrical and bathymetrical map of the Western Mediterranean and surrounding countries, curved to show the figure of the earth; (2) relief map of a part of the valley of the Semois in the neighbourhood of Rochepaut, Belgian Ardennes. These maps have been prepared under the direction of Prof. Elisée Reclus by Mr. E. Patesson. The map of the Mediterranean, in aluminium, is drawn on the scale of 1 : 5,000,000. It is curved to show the exact figure of the earth. Elevations of land and depths of water are shown by a system of contours and tinting. The second map is in copper, and represents the relief of the district without exaggeration of the vertical scale, and with the surface features carefully laid down. Both maps are intended for educational purposes.

Pictures shown by Mr. Arthur J. Evans, F.R.S., illustrated excavations at Knossos, in Crete, and included: (1) general plan of the palace, showing excavations to June, 1902, and general section, showing successive terrace levels, &c.; (2) photographic views; (3) coloured drawings of palace frescoes.

Other exhibits were chloroformed calf lymph; method of its preparation (from the Government Lymph Laboratories), Dr. Alan B. Green; development and variation of the colour-pattern in Mexican species of lizards (Cnemidophorus and Ameiva), Dr. H. Gadow, F.R.S.; (1) true (glandular) hermaphroditism in a domestic fowl; (2) microscopic sections of prehistoric human bone, and of a prehistoric human urinary calculus, Mr. S. G. Shattock. Mimicry in butterflies from British East Africa and Uganda, Mr. S. A. Neave; specimen of Trypanosoma found by Dr. Castellani in cerebro-spinal fluid from sleeping sickness patients (Uganda), Dr. Aldo Castellani; specimens of a remarkable radiolarian of complex structure, Dr. G. H. Fowler; restored models of extinct fishes, the Director, British Museum (Natural History); preparations illustrating the cell-phenomena met with in apogamy, Prof. J. B. Farmer, F.R.S., Mr. J. E. S. Moore, and Miss L. Digby (see p. 71); remains of pigmy elephant and pigmy hippopotamus obtained from caves in Cyprus, Miss Dorothy M. A. Bate (see p. 71); (1) photographs illustrating the late eruptions in St. Vincent and Martinique; (2) volcanic dusts, ashes, and other ejecta of the West Indian volcanoes, West Indies Volcanoes Committee of the Royal Society; micrographs of volcanic dust from Mount Soufrière, St. Vincent, eruption, May 8, 1902, Mr. Thomas Andrews, F.R.S.; (1) the experimental demonstration of the curvature of the earth's surface recorded by photography; (2) photograph of ship hull-down at sea, Mr. H. Yule Oldham.

During the evening lantern demonstrations were given by Sir Benjamin Baker, K.C.B., F.R.S., illustrative of the Nile Dam Works, and by Prof. Harold B. Dixon, F.R.S., on the analysis of explosion flames by photography. The latter demonstration included (1) photographs of explosion flames, taken on very rapidly moving films, showing the genesis of the explosion-wave as the flame travels from the point of ignition, and the influence of reflections from the ends of the tube; (2) photographs of sound-waves moving through the explosion-flame, by which the approximate temperature of the flame may be calculated.

COOPERATION IN ASTRONOMY.

THE suggestions contained in the subjoined extracts from a paper by Prof. E. C. Pickering on "The Endowment of Astronomical Research," recently issued from Harvard College Observatory, will, we hope, be taken up by one of the many generous benefactors of science and higher education in the United States. The fundamental idea is the organisation of the forces which exist for the advancement of knowledge of astronomy. Many gifts have been made to astronomy in the United States, but in some cases the results have been disappointing, because the donors have not consulted astronomers as to the best way to promote scientific advance.

Imposing observatories are useless without instruments, and fine telescopes and spectroscopes depend upon "the man at the eye end" for the return they will give for the expenditure upon them. To obtain the best results, the astronomer with original ideas and progressive spirit should be placed in a position where he can carry on his work to the best advantage, and instruments should be used by men who require them for the increase of knowledge. This is the object of the plan proposed by Prof. Pickering. Money, materials and men available for astronomical research are to be brought together so that each is used to the best advantage.

In the United States, where the liberal benefactor has endowed scientific work to an extent unparalleled in any other country, the scheme will probably be taken up. Though the gifts to higher education and research have been so many and generous in the past, Prof. Pickering remarks that owing to the industrial prosperity of America "gifts may be expected ten times as large as those of the last century, during which Harvard College Observatory received three funds exceeding one, two, and three hundred thousand dollars respectively." He has therefore considered how a gift of one or two million dollars, if given to Harvard for astronomical purposes, could be best expended. The cooperative scheme of work suggested is one which would certainly accelerate progress, and the results attained would be such that enlightened donors could see and appreciate them.

There would be no attempt to interfere with independent work; in fact, the scheme aims at promoting such work and providing for the publication of the results. The Carnegie Institution was established with the same objects, and has already provided the means for carrying on important inquiries in various branches of science. Prof. Pickering's plan is worthy of the broad views associated with Harvard College Observatory, and we trust that means will be forthcoming to carry it into effect. We reprint part of the circular in which the plan is put forward.

The following outline of a plan will show how a sum of fifty to one hundred thousand dollars annually could be advantageously expended for astronomy by this observatory. A board of advisers, consisting of several of the leading astronomers of the country, would be appointed which would meet once a year, or at first oftener, to consider how the available income could be best expended in order to receive the greatest scientific return.

This board would consist partly of the directors of observatories who could expend portions of the income themselves, and partly of older astronomers who, having retired from active work, could decide without prejudice how the income could be expended to the best advantage by others. They would have authority to add temporarily to their number astronomers who might be invited to participate in any special work, and who could thus take part in their discussions on equal terms. All expenses of this board would be paid from the income, and except for clerk hire these would be almost the only executive expenses. A circular letter would be sent to all astronomers, inviting application for aid and suggestions for methods of expending the income. If possible, close relations would be established with the trustees of all the research funds which could be used for astronomical purposes, to increase efficiency and avoid duplication of work. The most important duty of the board of advisers would be to consider each year what departments of astronomy were being neglected, and to secure the needed observations, or if necessary undertake them themselves, or see that they were made at Harvard. As every astronomer is inclined to undertake the work which attracts him most, especially interesting investigations are likely to be duplicated unnecessarily, while laborious or unattractive investigations are neglected. This is particularly objectionable, since in astronomy, a science of observation and not of experiment, an opportunity once missed can in many cases never be recovered. As an example of needless duplication, fifty observatories agreed to observe the planet Eros during its opposition in 1900, but, so far

as known, only two or three have made the reductions needed to render their observations of any value. When a plan was decided on, it would be discussed by the entire board, and it is obvious that their combined experience would render serious mistakes less probable than when all depends on the judgment of a single individual, as is now the case. They could find the best man for a given research, and give him the best possible facilities for carrying it on. They could undertake larger and more difficult researches than a single observatory could attempt. It would be the power of many, instead of one, and of large, instead of restricted, resources. The opportunity offered to such a board of advisers, having control of the principal instruments of the country and a large sum of money available to set at work any particular corps of astronomers, ought to secure results far beyond those attainable at any existing observatory. All the advantages of a trust would be secured, with none of its objections. No one could object to a trust in wheat, for example, if its only object was to increase the quality and quantity of the crop, and to furnish it to consumers at the lowest rates, also to aid those not members of the trust in every possible way. In the present case, these conditions would be enforced by a body of men entirely unprejudiced, the Corporation of Harvard College. It is universally admitted that in the industrial arts there is a great advantage in cooperation, and in carrying on work on a very large scale. The same remarks apply to scientific investigation, with the added advantage that the supply and demand are indefinitely great, so that the market can never be glutted.

Apart from the advantages to astronomy of such a plan as is here outlined, it is believed that it would serve as a valuable example to the other sciences, and the moral effect of promoting uniformity of purpose, and friendly aid to one another by astronomers of all countries, would encourage other donors. An incidental advantage of this plan is that it could be tried on a small scale, as for a single year, and the donor could thus see what results were likely to follow if he made the plan permanent.

Of course, every effort would be made to establish the closest relations with astronomers in general, as the object of the institution could not be attained if the work done was not regarded as advancing astronomical research in the best way. Much might be accomplished through existing societies and periodicals. Another matter of especial importance is that when an astronomer is aided who is qualified to carry on a work in the best way, no restrictions should be made on the appropriation which would in any way interfere with his obtaining the best results.

It will be noticed that this plan differs from those governing existing funds for research in being active and not passive. While the trustees of other funds wait for applications, and then consider what appropriations can be made, it would be the aim of the advisers of this fund to learn what astronomers desired aid, what instruments now unused were available for work, and what valuable material remained unpublished and consequently useless for lack of means. Its special object would be to determine the needs of astronomers, to find what subjects were being neglected, especially those the usefulness of which would be lost by delay, and, if possible, to take the necessary steps to secure their execution. Much might be done with existing funds, and it is believed that the trustees of such funds would, in many cases, welcome the means of expending the available income to the best advantage. The opportunities for good work are far in excess of the present means for supplying them. Even the great resources of the Carnegie Institution will be able to respond to only a portion of the excellent applications made to it for aid.

It is most important that unnecessary delays should be avoided. It often happens that an astronomer could undertake a piece of work at once, perhaps during a summer vacation, while after a delay of several months he might be unable to carry it out, or might have lost many of the details then fresh in his mind. This is still more important with large pieces of work. A delay of several years may render a mature astronomer incapable of completing a work, which if undertaken at once, he could carry out with his greatest vigour and skill.

These remarks apply with equal force to the present plan of work. The Harvard Observatory has now the appliances, both intellectual and physical, for undertaking large pieces of work. Several of the leading astronomers of the country are in sympathy with such a plan for cooperation, so that the important methods of organising and initiating a system could be devised at the present time under very favourable conditions which may not prevail a few years hence, although the plan once started could easily be carried on by others. It therefore seems wise to make a beginning, however small, hoping to show results that will lead to an early fulfilment of the entire plan.

The undersigned, therefore, invites the astronomers of this and other countries to send to him applications for aid. A brief statement of the case in form for publication should be made, generally not exceeding two hundred words in length, with an estimate of the cost, and any additional necessary details. If publication is not desired, it should be stated.

The undersigned will then use his best efforts to secure the execution of such of these plans as commend themselves to him, reserving the right to omit all others. If the list of applications received seems worthy of it, he will publish and distribute it to possible donors, and will endeavour to secure its publication elsewhere. He will also bring such applications as commend themselves to him to the attention of the officers in charge of the following research funds, with which he is officially connected:—

Rumford Fund of the American Academy. Principal, 52,000 dollars. Income available to aid American investigators in light and heat.

Elizabeth Thompson Science Fund. Principal, 26,000 dollars. Income available for investigators of all countries in all departments of science. Appropriations seldom exceed 300 dollars.

Henry Draper Fund of the National Academy. Principal, 6000 dollars. Accumulated income April 15, 1902, 1515·99 dollars. Available for investigations in astronomical physics, by citizens of the United States.

Advancement of Astronomical Science Fund of the Harvard College Observatory. Principal, 70,000 dollars, of which 10,000 dollars is now available as stated above. Income may be used for astronomers of any country.

When we consider the great sums at the disposal of the trustees of the Carnegie Institution, and the large unexpended balances of the various research funds of the National Academy, it is not probable that any really worthy investigation requiring only a few hundred dollars for its execution need fail for want of such a sum.

There is another direction in which the writer believes that a great astronomical return could be obtained for a reasonable expenditure of money, some of which is already available. There are, in the United States, many telescopes of large size, which are now in use during only a small portion of every clear night. It is believed that in many cases advanced students in astronomy would be glad to undertake systematic observations with such instruments for a salary equivalent to a fellowship. They would thus be enabled to continue their studies, and at the same time make valuable additions to our knowledge of astronomy.

Larger investigations may be carried on by the Carnegie Institution or by private gift. For such investigations the undersigned offers assistance to prospective donors, *if they desire it*. He will in that case secure for them the opinions of the leading astronomers of the country regarding any proposed investigation. A wealthy man, when making a large investment in an industrial enterprise with which he was not familiar, would always obtain the opinion of an expert, for which he would often pay a large sum. How much more important is it in a subject like astronomy, with which he is likely to be still less familiar, that he should learn the views, which would be given freely and without charge, of the principal experts in the country who have devoted their entire lives to the consideration of these subjects.

In brief, it is proposed to establish an institution in connection with the Harvard Observatory the aim of which should be to advance astronomy as much as possible by making appropriations under the combined advice of the leading astronomers of the country. Much attention would be paid to neglected subjects, especially to those which cannot be

provided for by later observations, to secure for persons properly qualified the use of powerful telescopes now idle and therefore useless, and, in general, to secure for the person best qualified for any given research the best possible means of carrying it on. It would provide means for co-operation, and would aim at the advancement of astronomy, regardless of country or any personal considerations. The cost of this plan, if fully carried out, would be less than that of a first-class observatory, and it could be fairly tried for a short time at a moderate expense. For success, it must be wholly unselfish and this condition permanently secured, the investments must be safe, and the net income large. It is believed that no guardian would more surely fulfil these conditions than the Corporation of Harvard College. EDWARD C. PICKERING.

THE ROYAL VISIT TO GLASGOW.

THE laying of the memorial stone of the new buildings for the Glasgow and West of Scotland Technical College by His Majesty King Edward on Thursday, May 14, is a gratifying indication of the importance now attached to an efficient system of technical education. The ceremony at the College was the first item on the programme of the Royal visit to the city, and, except as regards the weather, which was more lavish of the April shower than the May sunshine, was most successfully carried out. An hour before the arrival of the King and Queen upwards of 4000 guests had assembled on the site of the new buildings, and their Majesties, on stepping on to the royal platform, received a most loyal welcome. Lord Balfour of Burleigh, the minister in attendance on the King, introduced to His Majesty Mr. W. R. Copland, the chairman of the Governors of the College, and Mr. D. Barclay, the architect of the new buildings, and the laying of the memorial stone was immediately proceeded with. In thanking His Majesty, Mr. Copland recalled the fact that, so long ago as 1881, on the laying of the memorial stone of the Central Technical College of the City and Guilds of London, His Majesty was pleased to recognise the importance of educating persons destined to take part in the productive industries of the kingdom, and referred to the training of the intelligence of the industrial community as the great factor in retaining the position of Britain as a manufacturing nation. The King, in reply, expressed the great pleasure it had given him to lay the memorial stone; he had long recognised the importance of the work done by institutions of this kind, and hoped the building now to be erected would realise to the full the expectations of the governors.

In the course of the day their Majesties visited the University, the foundation stone of which they had laid on October 8, 1868. The Very Rev. R. H. Story, D.D., Principal and Vice-Chancellor of the University, the professors, lecturers and demonstrators, and a large body of graduates were assembled in front of the magnificent building on Gilmorehill, and in the name of the University the principal presented an address to His Majesty. In the address it was noted that, except on two occasions, in 1849 and in 1888, when Queen Victoria visited Glasgow, no Sovereign of Great Britain had seen this University since King James VI. visited it on his return to his ancient kingdom after succeeding to the throne of England. In his reply the King expressed his great gratification at having an opportunity, accompanied by the Queen, of renewing his acquaintance with the ancient University; he was deeply interested in the allusions to the visits of his predecessor King James VI. and of his august and beloved mother, Queen Victoria; he recalled with satisfaction his own share in laying the foundation stone of the noble building, and he earnestly desired that this and other universities as schools of higher learning might grow and prosper, and so advance the material progress of his people.

After His Majesty had replied to the address, the Deans of Faculties were presented to him by Lord Balfour.

The constitution under which the Glasgow and West of Scotland Technical College is now working dates from 1886, but the institution itself had its origin in Anderson's College, which was founded in 1796 under the will of John Anderson, M.A., F.R.S., professor of natural philosophy in the University of Glasgow, and is thus certainly the oldest institution of the kind in Great Britain, and probably in the world. Prof. Anderson was in many respects a remarkable man. The idiosyncrasies of his character brought him into frequent conflict with his colleagues in the University, but it is more pleasant to record that he seems to have been deeply impressed with the importance to the industries of the city of awakening in masters and workmen an intelligent interest in the scientific aspects of their trade. He made frequent visits to the local workshops, and took great pains to make himself familiar with local industries. It is well known that when James Watt had difficulties put in his way by the incorporation of hammermen of Glasgow he was appointed mathematical instrument maker to the University, and it was Anderson with whom he was most closely associated in this post. In furtherance of his aims Prof. Anderson inaugurated classes in the University designed to attract employers and workmen as well as the ordinary university students, and these he carried on until his death in 1796. At the present day, when technical education has assumed such a prominent position in the public mind, it is but fair to recall with gratitude the work of the man who may be justly named its pioneer.

On his death Prof. Anderson bequeathed all his means "to the public, for the good of mankind and the improvement of science, in an institution to be denominated 'Anderson's University.'" He directed that the management of the institution was to be vested in the Board of Trustees constituted under his will, and this Board continued in existence until 1886, when the institution was incorporated in the Glasgow and West of Scotland Technical College.

The first chair created was that of chemistry and natural philosophy, and was occupied by Dr. Thomas Garnett until 1799, when he was called to fill the first professorship in the Royal Institution. His successor in Glasgow was Dr. George Birkbeck, who formed a special class for "the gratuitous instruction of the operatives of Glasgow in mechanical and chemical philosophy," in the belief that "men should be taught the principles of the arts they practise." This class, which was named "the Mechanics' Class," separated in 1823 from Anderson's College and took the title of "Mechanics' Institution," the first of the many mechanics' institutions that marked the movement for the scientific education of artisans. In 1881 the Glasgow Mechanics' Institution changed its title to that of "The College of Science and Arts," and continued to maintain a separate existence until it was merged with the parent institution in the present Technical College.

The names of many eminent men are associated with Anderson's College. Among its professors were Dr. Andrew Ure, author of "The Dictionary of Arts and Manufactures"; Dr. Thomas Graham, afterwards Master of the Mint, for whom the honour is claimed of establishing the first laboratory for public instruction in chemistry in Great Britain; Dr. Thorpe, the present Director of the Government Laboratories; Dr. W. Dittmar; and Dr. G. Carey Foster, the present Principal of University College, London. Among its students were Dr. Livingstone; Lord Playfair; Dr. James Young, the founder of the Scottish oil industry; and Sir J. H. Gilbert, of Rothamsted. Lord Kelvin and his brother, Prof. James Thomson, were students of the Mechanics' Institution.

In 1886, by an Order of Her late Majesty, Queen Victoria, in Council, Anderson's College, the College of Science and Arts, the "Young" Chair of Technical Chemistry—founded

in connection with Anderson's College by its then president, Dr. James Young, referred to above—Allan Glen's Institution, and the Atkinson Institution were amalgamated to form the Glasgow and West of Scotland Technical College. The main object of the governors of the reconstituted institution has been from the first "to afford a suitable education to those who wished to qualify themselves for following an industrial profession or trade"; it is not the purpose of the College to supersede the ordinary apprenticeship, but rather to supplement it, and the courses for day students in engineering are arranged to permit of their spending the summer months in serving part of their apprenticeship, while devoting the winter months to college work.

The maintenance of the institution entails an annual expenditure of about 25,000*l.*, derived in approximately equal proportions from endowments, students' fees, Government grants, and grants from the Corporation of Glasgow and other public bodies.

The College work has hitherto been conducted in the buildings formerly occupied by the amalgamated institutions and in hired premises scattered over the centre of the city, but these have long been inadequate, and for some years it has been necessary to refuse admission to hundreds of students for lack of room. So serious is the want of accommodation that a gift of 5000*l.* by Mrs. John Elder to make provision for lectures of a popular character on descriptive astronomy cannot be utilised under existing conditions, and contemplated extensions in other directions are meanwhile impossible for similar reasons. In December, 1900, a meeting of the citizens was convened by the Lord Provost of Glasgow to consider the scheme which the Governors, after full deliberation on the various alternatives, had adopted for the erection of new buildings. A committee was formed to obtain subscriptions, and in less than two years a sum of nearly 180,000*l.* was raised.

The Governors appointed Mr. David Barclay, F.R.I.B.A., to be their architect, and they are satisfied that he has designed buildings admirably adapted to the purpose in view. They will consist of five large wings, two being parallel to George Street; the other three will be placed at right angles to them, and parallel to Montrose Street. The walls facing the streets will be of red Dumfriesshire stone; all the other exterior walls will be of white enamelled brick, thus securing a surface which will give the greatest amount of light to the rooms facing the three interior courts.

The following table indicates the main departments of the College, and, approximately, the space (in square feet) allotted to each:—mathematics, 5500; natural philosophy, 10,400; chemistry, 16,500; technical chemistry, 7500; mechanics, 10,000; machine design, 10,000; prime movers, 15,100; metallurgy, 4800; electrical engineering, 15,900; practical engineering, 4000; mining and geology, 3400; architecture and building construction, 7700; biology, 3200; industrial arts, 4000; workshops, 7900; bakery school, 2100; administration, library, general class-rooms, &c., 37,000.

The prime movers laboratory, the dynamo laboratory, and the practical engineering laboratory will be placed at the bottom of the interior courts, and will be lighted entirely from glass roofs. The chemical departments will occupy practically the whole of the top floor, and will contain several large laboratories and other similar rooms set apart for special purposes. The plan of confining each department to one floor has been followed throughout, with a view to promote efficiency in working.

The buildings will be the largest of the kind in Great Britain, and will cover nearly two acres; their cost, with the site, but exclusive of the equipment, will amount to about 210,000*l.* Meantime, contracts have been made for the erection of the first section of the buildings, comprising nearly three-fourths of the whole.

The inadequacy of the present buildings for the work of a technical institution has been long felt by teachers and students, but there are many scattered all over the world who have a grateful remembrance of the instruction and guidance they obtained in these old-fashioned rooms; there is every reason to hope that with improved facilities for work there will be quickened zeal to take advantage of them.

G. A. G.

NOTES.

WE are glad to know that steps have been taken to secure and erect a memorial of the late Sir George Stokes in Westminster Abbey. At a meeting of a joint committee of the University of Cambridge and the Royal Society, held on March 12, the Duke of Devonshire being in the chair, it was resolved that the authority of the Dean and Chapter of Westminster be requested to place a medallion relief portrait of Sir George Stokes in the Abbey of the same general character as the memorials of Darwin and other scientific men already there. A letter has since been received from the Dean of Westminster expressing his general assent to the proposal and his willingness to take detailed plans into consideration. Mr. Hamo Thornycroft, R.A., has undertaken to prepare a medallion, the material to be bronze, and the head to be in high relief. It is estimated that the cost of placing this memorial in Westminster Abbey will be about 400*l.*, and as there are doubtless many admirers of Stokes who would like to contribute to the fund being raised for the purpose of the memorial to him, a subscription list has been opened. The treasurers of the fund are the Vice-Chancellor of the University of Cambridge and the treasurer of the Royal Society. Subscriptions should be made payable to Messrs. Barclay and Co., Ltd., and should be sent either to them at their Cambridge branch or to the treasurer of the Royal Society.

THE two gold Hofmann medals, established in 1888 in connection with the seventieth birthday of August Wilhelm von Hofmann, for award to distinguished foreign men of science, have been conferred by the German Chemical Society upon Prof. Henri Moissan and Sir William Ramsay.

THE centenary of the announcement of the atomic theory by Dalton was celebrated at Manchester on Tuesday and Wednesday. We propose to publish an account of the celebration in our next number with an article upon the atomic theory.

THE Royal Society of Edinburgh will hold a conversazione in the rooms of the Royal Institution, Edinburgh, on Saturday, June 6.

AN International Exhibition will be opened at Athens on June 3, and will last six months. The British exhibits, as at present arranged, will occupy 500 square metres, and will consist mainly of engines, ship-models, and guns.

THE Central News Agency reports that, according to a despatch from the city of Mexico, the Colima volcano is again in active eruption.

DURING the week beginning June 1, Prof. J. J. Thomson, F.R.S., Cavendish professor of experimental physics in the University of Cambridge, will, says *Science*, give a course of lectures in the physical laboratory of the Johns Hopkins University on "A Theory of the Arc and Spark Discharges."

MR. W. L. SCLATER left England last week to resume his duties as director of the South African Museum at Cape Town. Before his departure he was presented with an address signed by nearly six hundred members of the Zoological Society, testifying to the tact and ability shown by him while occupying the post of secretary, to which he was provisionally elected.

A MARBLE bust of George Stephenson was unveiled at the railway station at Rome on April 23. The bust was presented by the Institution of Civil Engineers to the municipality of Rome as a supplement to the tablet placed in the vestibule of the railway station at Rome in 1881 to commemorate the centenary of the birth of the father of the railway system.

A general meeting of the British Academy was held on May 14, Lord Reay, the president, being in the chair. Papers were read by Dr. Edward Caird, Master of Balliol College, Oxford, on "Idealism and the Theory of Knowledge," and by Prof. W. M. Ramsay on "The Importance of a Systematic Exploration of Asia Minor (in conjunction with the recently formed societies for the same purpose in Austria and in Germany)."

We regret to record the death, on May 12, of Mr. William Talbot Aveline, at the age of eighty-one. He was engaged on the staff of the Geological Survey under De la Beche, as long ago as 1840. His early field-work was carried on in the region of the Mendip Hills and in South Wales; subsequently in many parts of North Wales, the western and midland counties of England, he personally surveyed large areas, while in later years he was called on to superintend the field-work in the Lake District. The maps and sections of the Geological Survey, especially in Silurian regions, form the chief records of his labours, for he wrote but little. He became a fellow of the Geological Society in 1848, and in 1894 he was awarded the Murchison medal in appreciation of his long-continued and careful labours in field-geology.

We learn from the *Athenaeum* that a Norwegian expedition, commanded by Captain Roald Amundsen, left Christiania a few days ago with the object of fixing the exact situation of the magnetic North Pole. The party are expected to be absent for four years, the route taken being by Lancaster Sound, Boothia Felix, where a magnetic observatory will be established for a period of two years under control of two members of the scientific staff, and back by the North-West Passage, Victoria Land, and the Behring Straits.

On Tuesday next, May 26, Prof. E. J. Garwood delivers the first of two lectures at the Royal Institution on "The Work of Ice as a Geological Agent"; on Thursday, May 28, Prof. J. A. Fleming commences a course of two lectures on "Electric Resonance and Wireless Telegraphy"; and on Saturday, May 30, Prof. S. P. Thompson begins a course of two lectures on "The 'De Magnete' and its Author." The Friday evening discourse on May 29 will be delivered by His Highness the Prince of Monaco on "The Progress of Oceanography," and on June 5 by Prof. H. H. Turner on "The New Star in Gemini." The extra discourse on June 19 will be delivered in French by Prof. Pierre Curie on "Radium."

A Paris correspondent states that on May 8, a balloon built for MM. Lebaudy made a notable performance. The balloon left the Moisson Aërodrome in the morning and returned to it after having navigated round Mantes at a distance of 10 kilometres. The performance was executed in 1h. 36m. by a circuitous way the length of which has been estimated as 37 kilometres. The length of the air-ship is 56 metres, and the volume 2300 cubic metres. The engine is a 40 horse-power. There were two persons on board, M. Juchmès, a well-known professional aëronaut, and a mechanician. The peculiarity of the balloon is that it has two screws working in the central part, and not a single propeller at some distance behind. There are two rudders behind at a distance of about 20 metres from the car, one for the vertical motion and the other for movement in a horizontal direction.

During the course of his speech at the opening of the Johnston Laboratories of the University College of Liverpool, of which a short account was given in these columns last week, the President of the Local Government Board made it clear that he at least understands fully the important part science has taken in the work of civilisation and progress. Mr. Long said that so long as he had the honour to occupy the position he now held he would do his best to secure on behalf of the Government of the day the utmost assistance that could be given to the advancement of science in all parts of the country. It seemed to him that the connection was very close between the development of science, and especially of that form of science which was known as preventive medicine, and the commerce for which this great country was so justly famous. There is no doubt of this intimate interdependence of scientific knowledge and commercial success, and Mr. Long did well to commend the people of Liverpool for having raised by donations to university education the sum of 200,000*l.*

At the anniversary meeting of the Royal Geographical Society on Monday, the medals and awards which are given annually for the encouragement of geographical science and discovery, and have already been announced (March 19, p. 469), were presented. In the course of an address the president said that Captain Sverdrup, in completing our knowledge of the Parry archipelago, had also completed our general knowledge of Arctic geography. The whole problem of Arctic geography had now been solved. There were many isolated pieces of work that would have to be undertaken, but none which would justify the dispatch of an expedition on a large scale. With regard to the Antarctic regions, he said that the German expedition had the great advantage of having selected one of the two best routes for Antarctic discovery. After giving a short summary of the position of the British expedition, the president said that the *Morning* must go south again next December, and for this purpose funds, amounting to perhaps 15,000*l.*, must be provided.

The fall of dust between February 21 and 23 last was observed over such an exceptionally extensive area of Europe, from Ireland eastward into Austria, that the phenomenon has attracted more than usual attention, and already a number of papers dealing with local falls have been written. On the May pilot chart, just published by the Meteorological Office, there is, however, an extremely interesting map of the area from the Equator to 55° N., and from 40° W. to 20° E., exhibiting at a glance the distribution of dust or sand, of mist, haze or fog, the mean barometric pressure for the five days February 18 to 22, and the wind direction recorded by observers out at sea. The accompanying letterpress shows that prior to the dust reaching Europe, sandstorms had interfered with the progress of the British Boundary Commission in Nigeria, south of the Sahara, and had also been experienced on the northern edge of the Sahara. At sea, off Africa, ships were hampered in their movements by the obscuration due to the great quantities of sand in the air, from the Gulf of Guinea to 30° W. and up to the Azores. The map shows very clearly that the wind about the Canaries, becoming easterly to south-easterly in direction on February 19, drove the dust-cloud to west and north-west, and near the Azores, the wind being south-westerly, the cloud was quickly carried north-eastward to England and Europe. It is deserving of notice that, according to the log of the R.M.S. *Briton*, keeping near the African coast, the sand was very dense, "huge quantities of red dust," with the wind at north-east, but a temporary change to south-south-west for ten minutes cleared the air immediately. On the wind going back into north-east, the sandstorm came over again. The steamer *Kirkby*, on the other hand, running westward from Madeira, had the dust fall with a south-east wind; when the wind changed to north the dust ceased.

A CORRESPONDENT of the *Times*, writing from St. Vincent on April 22, gives some interesting particulars of the Soufrière eruption of that date. Soon after daylight, he observed that inside of a quarter of an hour the enormous umbrella-like steam-cloud spread out enormously. At this time no noise was noticeable in the town. A little later, violent explosions occurred at frequent intervals. It soon became quite dark, but, following previous cases, everything began to go in the direction of Barbados. Fine metallic dust fell until next day, black and gritty, apparently magnetite. Châteaubelair did not suffer this time except for another deposit of sand and small stones. Georgetown suffered much, and large stones fell throughout the Carib country.

MUCH discussion has recently taken place with reference to the behaviour of the Weston galvanic cell as a standard of electromotive force. The observed anomalies appear to be dependent upon the behaviour of the particular concentration (14·3 per cent.) of the cadmium amalgam previously recommended for the standard form of the instrument, and are not connected with any change in the condition of the cadmium sulphate which enters into the composition of the cell. It seems to be now definitely established that with less concentrated cadmium amalgams the Weston element gives quite normal and trustworthy indications.

IN the *Sitzungsberichte der Berliner Akademie* Profs. Holborn and Austin describe some important experiments on the loss of weight of the platinum metals when heated to temperatures of 1000° to 1500° C. by means of an electric current. In the case of platinum, rhodium and iridium this loss of weight only takes place in an atmosphere containing oxygen, and is probably due to a chemical change. With palladium the phenomenon is independent of the nature of the surrounding gas, but depends very considerably on the pressure, the rate of loss of weight increasing as the pressure of the gas decreases. The behaviour of palladium agrees with the supposition that the loss of weight is simply due to sublimation.

WE have received from Dr. Jansen a short summary of the work already accomplished in the preparation of the "Technolexicon," to which we have referred on one or two occasions recently. Up to the present assistance has been received from 341 societies and more than 2000 industrial establishments and individuals. Of the societies, 272 are German, 42 English and American, and 27 French. An analysis of existing dictionaries, catalogues, &c., has given a list of something like one and a quarter million words, and it is expected that a large number more will be obtained from the note-books of collaborators, which will be called in during 1904. It is not expected that the dictionary will be ready for printing until the end of 1906.

PROF. LADISLAUS NATANSON has published in the *Journal of Physical Chemistry* for February a lecture delivered before the Cracow Academy of Sciences on "Inertia and Coercion." The author considers that the phenomena of nature can be divided into two classes, those which bear a character of permanence, and those which tend to subside. Under the first category he places the motions considered in the ideal systems of rational dynamics, and the equilibria of classical thermodynamics. There are, however, other cases in which the two classes of phenomena cannot be considered separately; these are studied in the subject of thermokinetics. Equilibrium is only a limit to phenomena, and to study what actually occurs in nature we must go on to study the laws which preside over their progress. In cases where a disturbance tends to subside, as in the diffusion of gases, the conduction of heat, and the flow of electricity, we find that the progress of the phenomenon is represented quantitatively by the flux of a certain quantity per unit time across unit surface. This flux depends in general on what may be called the stimulus of the phenomenon. This "stimulus" may give impetus to the flux, but it will in every case be largely employed in overcoming "coercion," a property which always tends to impede the flow, but does not in general (*e.g.* in the case of diffusion of gases) destroy it altogether.

IN the *Contemporary Review* for May, Mr. Frederick Soddy, whose name is well-known as a co-worker with Prof. E. Rutherford at the McGill University, Montreal, describes what may be referred to as the Canadian view of radioactivity. Briefly stated, this is to the effect that the radioactive thorium X, which is contained in ordinary thorium, and can be separated by precipitating the inactive thorium by means of ammonia, is a first decomposition-product of the unstable thorium atoms, that the radio-active emanations which are transmitted by thorium X to neutral gases, such as hydrogen and nitrogen, and which are condensed by cooling to $-130°$ C., represent a further stage in the atomic degradation, and finally it is suggested that helium —an invariable constituent of radio-active minerals—is possibly the last and stable product of the shattered thorium atoms. According to this view, which will not be received without an effort by chemists trained to believe in the conservation of matter and the immutability of the elements, the energy of radium is derived from the deflagration of a minute and unweighable proportion of the almost explosive radium atoms.

IN the *Nineteenth Century*, Mr. William Ackroyd, writing on "Radium and its Position in Nature," directs attention to the fact that radium not only has the highest atomic weight, but probably, in accordance with a well-known law, is also the rarest of the known elements. The close resemblance between Becquerel rays and X-rays is referred to, and it is suggested that the production of the former is analogous to the phosphorescence of calcium sulphide after exposure to sunlight. The possibility that an atomic bombardment may be the source of energy of radio-active bodies is, however, inferred from a reversed phenomenon observed by Prof. Graham Bell and Mr. Sumner Tainter, in which solids, liquids and gases are made to emit a musical sound under the influence of an intermittent beam of light pulsating 500 or 600 times in a second.

IN a paper dealing with the infection-powers of ascospores in the Erysiphaceæ (*Journal of Botany*, May), Mr. E. S. Salmon takes up a subject which has been almost untouched. It is known that conidial forms of apparently the same species are restricted in their power of germinating to definite and distinct host-plants, and thus there are differentiated a number of so-called biologic forms. Whether ascospores show a similar selective capacity for infecting host-plants is the problem which Mr. E. S. Salmon endeavours to elucidate.

AN article of considerable interest which appears in the *Transactions* of the Royal Scottish Arboricultural Society refers to the inception of the scheme for laying out tree plantations on the gathering grounds of waterworks. On the lands belonging to the Halifax Corporation, which took the lead in this matter, ash, sycamore and alder have been planted along with Scots pine and larch, but the intention is to leave the hardwood only as a permanent crop. Other papers which are of primary importance to foresters relate to the larch and its diseases, thinnings in planted spruce, and the injurious effect of smoke on trees.

THE study of ecological botany has not been so vigorously pursued during recent years in Great Britain as in other countries, but the few papers that have appeared have been the outcome of thoroughly sound work. A botanical survey of the West Riding of Yorkshire has been completed, and the results obtained by Dr. W. G. Smith and Mr. C. E. Moss for the south-western district are incorporated in an article published in the *Geographical Journal.* Both the descriptions and photographic illustrations are exceedingly good, but the main feature is the representation of the various formations on a map on the scale of two miles to the inch, which should be carefully studied by all ecological workers; also the origin and relationships of the types of vegetation are critically discussed.

No. 5 of the *Proceedings* of the Chester Society of Natural History contains a list of the species of Lepidoptera recorded from Chester and four adjacent counties, drawn up by Mr. G. O. Day, with the assistance of two other gentlemen.

WE have received vol. iv. of "El Peru," a work on the geology and mineralogy of that country published by the Geographical Society of Lima. It appears that by the decease of Dr. Antonio Raimondi in 1890, the publication of this work, which commenced in 1874, was interrupted. The present volume is based on that observer's manuscripts, which it has taken a long time to prepare for publication. The bulk of the volume is devoted to the rocks of the country, both igneous and sedimentary; but the latter part includes a series of miscellaneous observations, including the description of a lower jaw of *Mastodon andium* from a Peruvian locality. The work should be invaluable to Peruvian geologists and petrologists.

A VERY important and interesting contribution to the study of the venation of the wings of dragon-flies appears in No. 1331 of the *Proceedings* of the U.S. Nat. Museum, illustrated by no less than twenty-four plates and many text-figures. The author, Mr. J. G. Needham, treats the subject from a phylogenetic point of view, and claims to have discovered features in wing-development which will be applicable to insects generally, as well as others affecting the classification of dragon-flies. He finds, for example, that the same type of wing, in accordance with the needs of the mode of life, has been independently developed in totally different sections of the group. This, of course, largely affects the determination of fossil dragon-flies, which have been to a great extent named on the evidence of the wings, or portions of the same, and it is shown that in several instances these determinations are wholly incorrect. *Libellulium kaupi,* for instance, is probably not a dragon-fly at all, while *L. agrias* belongs to the Æschnidæ, the details of the specimen figured by Westwood being entirely different to those characteristic of the Libellulidæ.

VISITORS to the Natural History Museum will not fail to notice a great improvement in the appearance and instructiveness of the exhibits in the reptile and fish galleries, which were left at the death of Sir W. H. Flower in their original condition. Until the director undertook the rearrangement, the cases were crammed with a number of faded and "khaki"-coloured specimens, unaccompanied by any descriptive labels. The duplicate and superfluous specimens have now, for the most part, been weeded out, and those that are left placed so that they can be well seen by visitors. In many instances old specimens have either been replaced by new ones or have been painted up so as to give them, so far as possible, some sort of resemblance to the living animals; and this process of replacement and renovation is being actively continued. A large specimen of a thunny which has been for many years in the museum affords an excellent example of what can be done by judicious painting. The splendid colouring of the Malay python is displayed in a specimen presented by Mr. Rothschild, as well as by a second example, on which an artist was still engaged at the time when this was written. In the reptile gallery, which is in the more forward condition, descriptive labels have already been placed in several of the cases, in which the specimens have been removed from the old hideous sycamore stands and set on sanded ground-work.

THE fourth part of vol. lxxiii. of the *Zeitschrift für wissenschaftliche Zoologie* is entirely occupied by the first part of an exhaustive memoir on the structure of the cell, the author, Prof. E. Rohde, in this section devoting his attention to the nucleus and nucleolus. No less than nine beautifully coloured plates (some of which are double) illustrate this section of the subject. To the first part of the succeeding volume (lxxiv.) Herr E. H. Zietzschmann contributes an account of the morphology and histology of the scent-glands which occur on the face and limbs of different members of the deer family. Very full details are given of the nature of these structures in the greater number of the generic groups, and the existence of a small metatarsal gland in the elk is confirmed. It is perhaps a matter for regret that the author did not see his way to express any opinion as to the existence of an homology between the limb-glands of the deer and those of other ungulates. The scent-gland of the centipede *Iulus communis* forms the subject of an article by Dr. G. Rosse in the same fasciculus, which also contains papers on the spermatogenesis of Cœlenterata, and on the development of Dolomedes.

THAT our village ancestors were not devoid of artistic sense is apparent from many old articles of furniture that are bought up and treasured by the more wealthy classes. In a paper on the decorative arts of our forefathers as exemplified in a Southdown village in the *Reliquary* for April, Mr. W. Heneage Legge has given some interesting examples of beautiful objects still to be found in a single village, but the trend of modern ideas is to induce a dead monotony of machine-made shop goods. In the same journal Mr. F. W. Galpin gives an illustrated account of the Portland reeve staffs. These are notched quadrangular rods, by means of which the annually appointed reeve, or steward, keeps his account of the rents due to the King as Lord of the Manor.

MARRIAGE customs are generally interesting on account of the often rude symbolism that accompanies them; students of this branch of ethnology will find many marriage customs of various southern Indian tribes related by E. Thurston in *Bulletin* vol. iv., No. 3, of the Madras Government Museum. Ethnologists are fully aware of the value of the *Bulletins* of this museum, and the current number contains a mass of valuable material contributed by the energetic director of the museum. A short account of fire-walking in Ganjám does not record any new feature. Our schoolmasters are not likely to adopt any of the forty-two kinds of punishment inflicted on naughty boys in native schools.

WE have received the April number of the *Journal of Hygiene* (vol. iii. No. 2). Several papers deal with preventive medicine, *e.g.* the significance of the presence of the colon bacillus in ground waters, by Mr. Horton; the

distribution of the diphtheria bacillus in the throats of "contacts," by Dr. Graham Smith; and upon the correlation of several diseases of animals in South Africa, by Dr. Edington. Messrs. Graham Smith and Sanger discuss the biological or precipitin test for blood in its medico-legal aspects, and Messrs. Nuttall and Shipley complete their monograph upon the structure and biology of the Anopheles mosquito. The last is an important contribution, and is illustrated with some beautiful figures.

A SECOND, revised and enlarged, edition of Mr. H. M. Leaf's "The Internal Wiring of Buildings" has been published by Messrs. Archibald Constable and Co., Ltd. The new edition contains an additional chapter on electricity meters.

MR. EDWARD ARNOLD has published a revised edition of "A Course of Practical Chemistry," by Mr. W. A. Shenstone, F.R.S. This little book is intended as a laboratory companion for use with the author's "Inorganic Chemistry."

THE fourth volume of the "Petite Encyclopédie Scientifique du XX^e Siècle," viz., "La Chimie dans l'Industrie, dans la Vie et dans la Nature," by M. A. Perret, published by MM. Schleicher Frères and Co., of Paris, has reached a second edition.

WE have received a copy of "A Guide to the Early Christian and Byzantine Antiquities in the Department of British and Mediæval Antiquities," printed by order of the Trustees of the British Museum. The book runs to 116 pages, and is illustrated with fifteen plates and eighty-four wood-cuts. Visits to the Christian Room of the British Museum with this guide as a companion will, if the book has been previously studied, be full of interest. The guide, even without the visits, will prove of great value to teachers of history.

A SECOND edition of the "Life History Album," edited some years ago by Mr. Francis Galton, F.R.S., has been published by Messrs. Macmillan and Co., Ltd. The "Album" was, in its original form, the joint production of a small committee of medical men, but Mr. Galton has largely rearranged and rewritten the contents, so that the present volume may be regarded almost as a new publication. Convenient provision is made in numerous well-arranged tables for a record of the genealogy, description at birth, the life and medical history for each year from birth to a hundred years of age, and for records as to wife (or husband) and children. An appendix supplies tests of vision and nine charts on which to represent graphically the weight and stature for each year of life.

A SUPPLEMENTARY volume to the "Scientific Memoirs of Thomas Henry Huxley," edited by Sir Michael Foster and Prof. E. Ray Lankester, has been published by Messrs. Macmillan and Co., Ltd. In the preface to the new volume Prof. Lankester says, "when it was discovered that owing to a bibliographical obscurity we had omitted the later portions of Huxley's 'Survey Memoir' on fossil fishes from our collection, it became necessary to issue a supplement containing the important work which we had inadvertently passed over. The opportunity is taken to add three interesting essays by Huxley, which, . . . have considerable interest for zoologists." These essays are "Vestiges of the Natural History of Creation. Tenth Edition. London, 1853." "The Rede Lecture, 1883," and the "Inaugural Address. Fisheries Exhibition. London, 1883." The essays referred to are not contained in the published edition of Huxley's more general essays.

IN a recent number of the *Berichte* Carl Neuberg describes a method of resolving racemic aldehydes and ketones by means of an optically active hydrazine. The difference in solubility between the stereoisomeric hydrazones is very considerable, and on combining racemic arabinose with *l*-menthylhydrazine, it was found that the hydrazone of the lævorotatory *d*-arabinose readily crystallised out in colourless prisms, which were practically pure, whilst the hydrazone of the *l*-sugar remained in solution as syrup, which could not be crystallised.

THE wandering of a methyl group in the conversion of pinacone into pinacoline is a phenomenon that has long been familiar to chemists, and further illustrations have recently been given by Crossley in the case of the dimethyldihydroresorcins. Three further examples occurring in the antipyrin group of compounds are described by Knorr in the *Berichte*, and it is noteworthy that in every case the transference of the methyl radicle takes place from a $>C(CH_3)_2$ group. It would therefore appear that the reluctance of one carbon atom to carry two methyl groups is an important factor in bringing about this somewhat unusual type of change.

THE additions to the Zoological Society's Gardens during the past week include a Great Wallaroo (*Macropus robustus*) from South Australia, presented by Mr. T. Becket Birt; a Black-crested Eagle (*Lophaëtus occipitalis*) from West Africa, presented by Mr. A. Boyd; a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, a Schneider's Skink (*Eumeces schneideri*), five Common Skinks (*Scincus officinalis*), four Common Chameleons (*Chamaeleon vulgaris*) from North Africa, six Hispid Lizards (*Agama hispida*) from South Africa, a Naked-necked Iguana (*Iguana delictissima*) from Tropical America, two Seven-banded Snakes (*Tropidonotus septemvittatus*), a Mocassin Snake (*Tropidonotus fasciatus*), two Testaceous Snakes (*Zamenis flagelliformis*), a Hog-nosed Snake (*Heterodon platyrhinos*) from North America, four Gallot's Lizards (*Lacerta galloti*), four Atlantic Lizards (*Lacerta atlantica*) from the Canary Islands, deposited; a Cape Zorilla (*Ictonyx zorilla*) from South Africa, purchased.

OUR ASTRONOMICAL COLUMN.

NOVA GEMINORUM.—*Bulletin* No. 19 of the Yerkes Observatory is devoted to the observations of Nova Geminorum which have been made since the telegram announcing its discovery was received on March 27.

Prof. Hale records the colour of the Nova as "a strong red," and when in the best focus of the 40-inch telescope there is a decided crimson glow around the image for about 2" or 3", which is not present with the images of the comparison stars. Prof. Barnard found that with the 40-inch refractor the focus of the Nova did not differ appreciably from that of the surrounding stars.

Magnitude observations show a decrease from 8·51 on March 27·715 to 8·96 on April 4·583, with a secondary maximum of 8·76 intervening on March 30·673 (H.C.O. scale of magnitudes).

Two of the prisms of the Bruce spectroscope were removed and a special camera constructed on March 28, and the spectrum of the Nova photographed the same night with an exposure of 3h. 12m. In the spectrogram obtained Prof. Frost has found a band extending from about λ 4598 to λ 4696 (mean about λ 4647), and a very strong $H\beta$ line having its mean value at λ 4862, with two narrow bright maxima near the less refrangible end at about $\lambda\lambda$ 4877 and 4882. A less refrangible band extends from λ 5647 to λ 5685 (mean at λ 5666), and another from λ 5729 to λ 5775 (mean about λ 5752); a sharp boundary on the violet side of the latter suggests the presence of a dark band.

The kind of plate used is not very sensitive at about λ 5000, and this may account for the absence of the band λ 5016, which, however, is exceedingly faint in this Nova. Hγ is present, but scarcely strong enough to measure, and merges into a brighter band which extends from λ 4347 to λ 4371 (mean at λ 4359).

A reproduction of the spectrogram is given, and it is seen that the spectrum corresponds to those of Nova Aurigæ and Nova Persei at the later stages of their development.

A very faint bright band in the spectrum of Nova Geminorum in the region of the chief nebula lines is far too weak to measure.

PARALLAX OF THE BINARY SYSTEM δ EQUULEI.—Mr. W. J. Hussey publishes in *Bulletin* No. 32 of the Lick Observatory the results of his calculation of the parallax of δ Equulei, based on the micrometrical and spectroscopical measurements made at the Lick Observatory during the past three years. The method pursued is theoretically absolute, for in no way is the result dependent upon the assumption of values for comparison stars, as it is in the ordinary method of calculating parallax.

The formula used was published by Prof. A. A. Rambaut (*M.N.* March, 1890), and gives the absolute parallax of a system when the elements of the orbit, the relative velocity of the components in the line of sight, and the orbital velocity of the earth at the time are known.

The determination of the elements of the orbit made at Lick has led to the adoption of 5·7 years as the periodic time of revolution; using this value for the period, and taking the mean distance as 0″·28, the eccentricity as 0·46, the apastron and periastron distances as 0″·409 and 0″·151 respectively, the relative velocity in the line of sight, determined by the observers using the Mills spectrograph, as 20·5 miles per second, and the orbital velocity of the earth at the time as 18·2 miles per second, Mr. Hussey obtains

$$\pi = 0''\cdot071$$

as the parallax of this system, but states that this is probably not the final value, for the elements may be appreciably modified during the critical observations it is proposed to make during the next three years.

Taking this value for the parallax and the mean distance and period given above, the mass of the system becomes 1·89, the mass of the sun being taken as unity, and, as the components are not quite equal in magnitude, the brighter may have a mass equal to, but not greatly exceeding, that of the sun. The mean distance of the components is about four times that of the earth from the sun, but, owing to the great eccentricity of the orbit, the actual distance at periastron is just more than twice, and at apastron about five times, that unit. As the spectra of the components are both of the solar type, and as their masses are comparable with that of the sun, it might be reasonably assumed that their densities do not differ to any great extent from the density of that body.

A REGULATING OR RECORDING THERMOMETER.

A THERMOMETER which is capable of regulating the temperature of a room with considerable accuracy, or of keeping a continuous record of the temperature, is frequently required in laboratory work. Such a thermometer is described in the present article. Although there is little essentially new in its construction, the details on which success depends are the result of considerable practical experience, and as the manufacture of such an instrument should be within the powers of most laboratories employing a mechanic, it has been thought desirable to publish an account of it.

The estimation of temperature in this thermometer depends on the alteration in shape of a piece of flat brass tubing bent into spiral form and filled with a liquid possessing a large coefficient of expansion. If one end of the tube is fixed, the motion of the other end, magnified by a suitable arrangement of levers, serves as a measure of temperature. As the thermometer is intended for use within a range of temperature of at most three or four degrees, we are not concerned with the equality of the graduations per degree at different parts of the scale.

The illustration (Fig. 1) shows the general appearance of the thermometer arranged as a recording instrument. The brass tubing of which the spiral is formed has a section in the shape of a very flat ellipse, the longer diameter being ⅞ inch, the shorter 3/16 inch, while the thickness of the wall is 0·02 inch. The tube is bent into the spiral form by filling it with melted resin and bending it round a cylinder 8 inches in diameter, on which is cut a spiral groove. After the resin has been removed by heating the tube, brass plugs[1] are soldered into the ends, each plug having a central hole for the purpose of filling the tube with liquid. In the thermometer illustrated, these holes are shown closed by steel screws. A simpler and more efficient plan is to solder a short length of lead tubing into the brass plug. Then, when the thermometer has been filled with liquid, the end of the lead tube is pinched together and soldered. The spiral can thus be hermetically sealed without loss of liquid.

In order that the thermometer may acquire the temperature of the surrounding air as rapidly as possible, the surface is increased by soldering to the spiral a strip of thin sheet copper about four inches wide. The whole is painted dead black.

For filling the tube creosote has been found to answer well. The process of filling the tube is the most troublesome part of the work, as it is difficult to get rid of the air bubbles which cling to the interior. While it is being carried out the tube should be placed in melting ice.

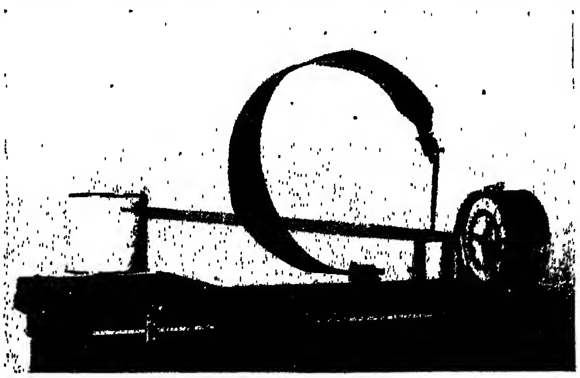

FIG. 1.—Recording Thermometer.

Funnels may be attached to the open ends of the spiral to facilitate the introduction of the liquid. When the tube is nearly full, liquid should be poured into either end in turn until the creosote rises in the other funnel free from air bubbles.

When the tube has been hermetically sealed, it is ready for attachment to the stand. Instead of fixing one end of the tube directly to the base board, it is fastened to one flap of a common brass hinge, the other end of which is screwed to the board. A hole is tapped in the upper flap and fitted with a screw the point of which bears against the lower flap, thus providing an adjustment for the distance between the two. This is a very simple method of giving a small alteration to the position of the fixed end of the spiral, and so adjusting the pen to any desired height on the recording cylinder.

The free end of the spiral is attached by a connecting rod of thin aluminium to a brass lever, half an inch in length, fixed to the spindle that carries the tracing arm. The length of the light arm which carries the pen is sixteen inches. Thus the actual motion of the end of the spiral is multiplied by the factor 32 at the recording drum.

The bracket carrying the spindle is formed of two uprights of thin sheet brass, screwed and soldered to a thicker base plate. The spindle itself is made of steel wire about three-sixteenths of an inch in diameter; the ends forming the pivots are turned down to a somewhat smaller diameter and ground into holes bored in the uprights. On the outer side of each upright is screwed a short length of flat steel

[1] The plugs should be of drawn brass, as it is found that creosote gradually percolates through cast brass.

spring, which bears against the projecting point of the spindle and so controls any lateral movement.

In addition to the recording cylinder a second clock will be noticed in the illustration. This was introduced because it was found that the pen was inclined to stick to the paper, so that the full range of temperature was not recorded. The clock once in every minute draws the pen away from the paper, so that it is free to take up its natural position. Hence the trace is made up of a series of dots instead of being a continuous line. The minute hand of the clock is replaced by a wheel in which sixty teeth are cut. Every minute one of the teeth engages with a short pin supported by a flat steel spring. When this pin is pushed aside it draws after it one of the springs referred to above as pressing against the point of the spindle. The spring at the opposite end of the spindle consequently comes into play and pushes the spindle in the direction of its length, thus relieving the pen from the paper.

In this thermometer the motion of the pen for a change in temperature of one degree Fahrenheit is about one inch (4·5 cm. per degree C.) at ordinary temperatures.

The thermometer selected for description is adapted for securing a continuous record of temperature. When it is desired to use such a thermometer to regulate the temperature, the pen may be replaced by a platinum point which is arranged to complete an electric circuit by contact with a platinum terminal or by dipping into a mercury cup. The current so set up may be used to operate a relay, and so switch on a stronger current, if heating by electricity is employed, or it may actuate some suitable mechanical arrangement for regulating the supply of gas to a stove. When it is necessary to maintain a uniform temperature for days or weeks together, it is most important that the sparking which takes place at the contact should be as far as possible reduced, otherwise the surfaces may become so contaminated that contact is uncertain, or in the case of platinum contacts may fuse together so that the contact is never broken. These are difficulties which those who have worked with such arrangements will appreciate. To overcome them it is well to reduce the current through the contact to the smallest possible value, and to place in parallel with the electromagnet which will form part of the circuit a non-inductive resistance. This resistance may be kept comparatively small, even at the expense of a somewhat larger current. A condenser inserted between the points of contact may be of service, but is not so effective as the plan mentioned.

It may be of interest to give some account of the success which has attended the use of these methods of regulating temperature in connection with the Blythswood dividing engine. The engine is placed in a detached building in a room fifteen feet long, ten feet wide, and ten feet high. Local conditions render it impossible to make use of a cellar. The room has double windows and shutters; it is warmed by two gas stoves, of which one is controlled by the regulating thermometer. During the greater part of the year this room can be kept at a temperature of 60° F., the variation in temperature being not more than one degree.

The controlling thermometer in this instance actuates, by an electromagnetic release, clockwork which supplies the necessary power for turning the gas on or off.

The dividing engine is enclosed in a wooden case inside this room. Originally the interior of the case was heated by electricity under the control of a regulating thermometer. The variations in temperature that were introduced by this method were sufficient to produce disastrous results in cutting a diffraction grating. Accordingly the case was surrounded with a lining of six inches of wool, and all the arrangements for securing a uniform temperature were made in the room outside. When this was done it was found that the temperature inside the case fell slowly but continuously. This was shown to be due to leakage of heat through the stand of the machine, which rested on a large stone block. To prevent this a space was cleared round the bottom of the stand, and this space was kept at a uniform temperature by electrical heating. This precaution was found to be effective, and the temperature of the case can now be kept constant with very considerable accuracy, the variation in four or five days not amounting to more than two-tenths of a degree Fahrenheit.

H. S. ALLEN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Public Orator, Dr. Sandys, spoke as follows on May 14, in presenting Mr. Robert Bell, LL.D., F.R.S., Director of the Geological Survey in Canada, for the degree of Doctor in Science *honoris causa*:

Magnum profecto est provinciae maximae penitus explorandae et scientiarum terminus latius proferendis vitam suam totam dedicasse. Salutamus virum, qui per annos plus quam quadraginta provinciae maximae Canadensis flumina, lacus, montes, campos denique latissime patentes exploravit; ibi locis plurimis nomina primus imposuit, et, ipse mortalium modestissimus, flumini a se primum indagato suum nomen ab aliis inditum audivit. Atqui nomen suum non in aqua scriptum, sed provinciae tantae in saxis potius insculptum reliquit; regionis illius immensae geologiam, geographiam, biologiam, archaeologiam libellorum in serie longa illustravit, et non modo provinciae ipsius terminos ubique definivit, sed etiam scientiarum fines ubique propagavit.

Duco ad vos Reginae Universitatis Canadensis doctorem, Societatis Regiae Londinensis socium, provinciae Canadensis exploratorem indefessum, ROBERTUM BELL.

A university lectureship in mathematics, stipend 50*l*. a year, is vacant by the election of Prof. Larmor to the Lucasian chair. Candidates are to send their names to the Vice-Chancellor by June 3, with statements of the branches of mathematics on which they are prepared to lecture.

In a report on the administration of the engineering laboratory it is proposed that two readerships, one in mechanical engineering and one in electrical engineering, should be established for Mr. Peace and Mr. Lamb, the present demonstrators; that two new university demonstrators should also be appointed, and that, in addition to their stipends, each of these should receive certain payments from the fees of students receiving instruction in the department. The growth of the latter under Prof. Ewing's direction may be gathered from the fact that in 1892 the number of students was 39, and the fees 546*l*., while in 1902 there were 211 students, who paid 5005*l*. in fees. In the present year there are twelve teachers, in addition to the professor and the two demonstrators, engaged in the work.

The syndicate report that the new building for the medical school is almost completed, and that the last stone of the Humphry Museum has been laid. A sum of 8062*l*. is required for fittings, furniture, electric lighting, and heating appliances.

The discussion in the Senate on the proposed reestablishment of the professorship of surgery turned chiefly on the question whether or not full residence should be required of the professor. If non-residence were permitted, a smaller stipend might suffice, and the field of choice might be widened. Prof. Liveing, Prof. Woodhead and others urged strongly that the professor's usefulness would depend on his being resident in the University.

MR. EDWIN EDSER has been appointed head of the physical department of the Goldsmiths' Institute, New Cross.

A CONVERSAZIONE of the Parents' National Educational Union will be held at the Kensington Town Hall on Monday, June 8. The Countess of Aberdeen will preside, and a paper will be contributed by Miss Mason, founder of the Union.

THE Court of Governors of University College, Sheffield, has adopted resolutions to the effect that in the interests of higher education in the city and district it is essential that Sheffield College shall have the powers and *status* of a university similar to those granted to Birmingham, Liverpool, and Manchester, and also that application be made to the Privy Council for a charter.

THE Secretary of State for India has appointed a small committee to inquire and report to him on the question of the expediency of maintaining the Engineering College at Coopers Hill, as a Government institution for the supply of officers to the Public Works Department in India. The committee will be composed as follows:—Sir Charles Crosthwaite, Sir James Mackay, G.C.M.G., Sir William Arrol,

M.P., Sir Arthur Rücker, and Sir Thomas Higham, K.C.I.E., with Mr. J. E. Ferard, of the India Office, as secretary.

THE new science rooms of the Colston's Girls' School, Bristol, were opened on Friday last, May 15, by the Right Hon. Henry Hobhouse, M.P. The new building comprises three rooms, about 30 feet by 26 feet, and one smaller. The lecture room will be largely used for the study of botany, and is provided with a small conservatory, or window box, in which experiments, such as those showing the process of germination, will be carried out. In the chemistry laboratory benches are provided at which girls will work in sets of two, and each set will have a balance on side benches close at hand. The physics laboratory is on very much the same plan as the chemistry room. Mr. Hobhouse, in the course of his speech, remarked that the education of girls was of the highest importance, not only in order to fit them for their domestic duties, but also to provide good women teachers. Prof. Armstrong hailed the opening of the new science rooms as a proof that science, once almost neglected, was now considered a necessary part of a liberal education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 26.—"On the Cytology of Apogamy and Apospory. (1) Preliminary Note on Apogamy." By J. B. **Farmer**, F.R.S., J. E. S. **Moore**, and Miss L. **Digby**.

The phenomenon of apogamy is exhibited when the young fern-plant springs directly from the tissue cells of the prothallium generation, instead of arising as the result of segmentation of the egg within the archegonium. It has been regarded as a "short cut" in the life-cycle, and some theoretical importance has been attached to it in connection

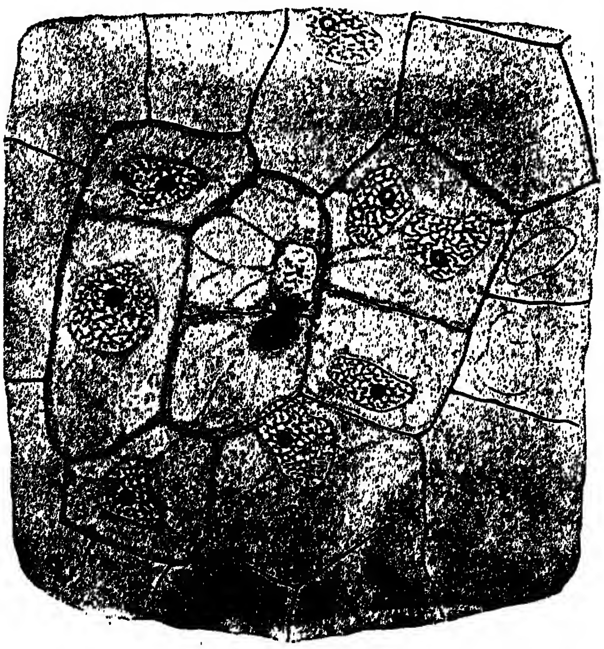

FIG. 1.—Group of prothallial cells with migrating nuclei.

with the relationships believed to exist between the gametophyte and the sporophyte, that is, between the prothallium and the fern-plant. Now it has been known for some years that the nuclei of these two generations exhibit a constant difference *inter se* of such a nature that each sporophyte nucleus contains twice as many chromosomes as do the individual nuclei of the gametophyte.

Evidence is brought forward to show that this nuclear change is brought about, in the apogamous development, by the migration of a nucleus to an adjacent cell, and its subsequent fusion with the nucleus of that cell. A considerable number of instances were observed in which single cells contained two nuclei, and when this was the case, one of the contiguous cells was always seen to be destitute of a nucleus. Instances of the transit of the nuclei through the walls were also seen. Further, the nuclei of some of the cells in the region where these occurrences were discoverable could occasionally be met with in stages at which it was found possible to estimate the number of chromosomes. In such cases these were double the number of those of the ordinary prothallial nuclei.

These facts lead to the inference that we are dealing with an irregular kind of fertilisation, or, at any rate, with a mechanism for doubling the nuclear chromosomes that is practically identical with what is seen in normal fertilisation. In the latter case the double number is arrived at by the addition of the chromosomes of the sperm-nucleus to those of the nucleus of the egg.

The annexed figure illustrates (1) two cells in which the nucleus of the one is passing through the parti-wall, and apparently fusing directly with the other nucleus; (2) a cell with two nuclei, one of which has been derived from the cell at the top right-hand corner of the figure.

May 7.—"Preliminary Note on the Discovery of a Pigmy Elephant in the Pleistocene of Cyprus." By Dorothy M. A. **Bate**. Communicated by Henry Woodward, LL.D., F.R.S., F.G.S., V.P.Z.S., late Keeper of Geology, British Museum, Natural History.

The elephant described was discovered by the author in 1902 during a search for bone-caves in the Kerynia Range in the north of the island. The collection obtained chiefly consists of a series of teeth, all procured from a single deposit, which also contained a very much larger quantity of the remains of *Hippopotamus minutus*.

The teeth of the Cypriote elephant are considerably smaller than those of *Elephas mnaidriensis*, the largest of the Maltese forms, and are also slightly inferior in size to those of *E. melitensis*. As a general feature it may be said that the molars from Cyprus are more simply constructed than those of the last-mentioned species, showing a slighter tendency to "crimping" in the enamel and in being less inclined to develop the mesial expansion of the plates of dentine so characteristic of those of *E. africanus*. Taking into consideration the several characters in which the teeth of the Cyprus form differ from those of all hitherto described dwarf species (putting on one side *E. lamarmorae*, the teeth of which are unknown to science), as well as the distinct habitat of the animal, it is believed to be specifically distinct, and it is therefore proposed to name it *Elephas cypriotes*. The discovery of this pigmy species is interesting in comparison with those from Malta and Sicily, and the occurrence of these different, though apparently closely related, small races of elephants in widely separated islands of the Mediterranean lends probability to the theory that this is a case of independent development along similar lines, the result of similar conditions of existence.

Physical Society, May 8.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Mr. T. H. **Blakesley** exhibited and described a spectroscope of direct vision, of one kind of glass, and of minimum deviation for every ray that comes into the centre of the field of view. The refracting angles are such that the cosines of half the refracting angles are equal to half the index of refraction for the ray which is to have no deviation. The first prism is right-angled, and has one angle equal to the refracting angle calculated by the above rule. The second prism and the third possess the refracting angle so obtained, and the fourth is similar to the first. The plan adopted can be extended by employing more than one of the arrangements described, in sequence.—Prof. J. D. **Everett** read a paper on the mathematics of bees' cells.—Mr. W. A. **Price** read a note on the coloured map problem. He referred to the fact that only four colours are required to colour a map on the surface of a simply connected region, such as a sphere, in such a way that two countries marching on a boundary line are coloured differently, and exhibited two models of anchor rings the surfaces of which were divided in each case into six sections, each of which marched with

the other five; and a model of a ring having a cross-bar or stud, the surface of which was divided into eight sections, each of which marched with the other seven. In the case of maps on such surfaces, at least six and eight colours would be required in the respective cases.—Dr. **Watson** read a note on the construction and attachment of galvanometer mirrors. It has often been pointed out, notably by Lord Rayleigh and Prof. Threlfall, that it is better to increase the sensitiveness of galvanometers and similar instruments by improving the optical system, rather than by pushing the electrical sensitiveness to extreme limits. When working with ordinary silver on glass mirrors difficulties arise in connection with the attachment of the fibre and the fact that it is necessary to use a varnish, which in all cases produces distortion. These difficulties have been overcome by using quartz instead of glass, and platinum instead of silver.

Mathematical Society, May 14.—Prof. H. Lamb, president, in the chair.—Lieut.-Colonel A. **Cunningham** announced the discovery of seven new factors of Fermat's numbers (2^{2^n}), viz. when n is 9, the factor $2^{16}.37+1$; when n is 11, the factors $2^{13}.3.13+1$ and $2^{13}.7.17+1$; when n is 12, the factors $2^{16}.397+1$ and $2^{16}.7.139+1$; when n is 18, the factor $2^{20}.13+1$; when n is 38, the factor $2^{41}.3+1$. In the cases of 9, 12, 18, the factors were discovered by Mr. A. E. Western; in the case of 11, by Lieut.-Colonel Cunningham; in the case of 38, jointly by collaboration of these authors with Rev. J. Cullen.—Dr. H. F. **Baker** communicated a series of notes:—(1) On the definiteness of quadratic forms with imaginary coefficients; (2) On a certain form of logical argument which occurs in the proofs of several fundamental theorems of pure mathematics; (3) On the summation of Neumann's series representing a potential determined by boundary values; (4) On the formation of the variant equation in the theory of differential equations; (5) On some points in the theory of continuous groups.—The following papers were communicated:—Mrs. **Young**, The surface representing all right-angled spherical triangles.—Mr. W. H. **Bussey**, Generational relations defining an abstract simple group of order 32736.—Mr. W. H. **Young**, (1) On skew surfaces contained in a linear congruence; (2) On closed sets of points and Cantor's numbers. In the last of these papers methods and results obtained by the author in a previous paper on the theory of sets of intervals are applied to the theory of linear sets of points. The theory of the higher transfinite numbers is avoided, but the transition to these numbers is shown to arise naturally, and a short account is given of the most recent work on this subject.

NEW SOUTH WALES.

Linnean Society, March 25.—Mr. J. H. Maiden, president, in the chair.—The president delivered the annual address, which was devoted chiefly to the consideration of the principles of botanical nomenclature.—The newly-elected president, Dr. T. Storie Dixson, then took the chair, and the following papers were read:—A monograph of the Australian Membracidæ, by Dr. F. W. **Goding**. In studying this group, twelve genera, represented by thirty-five species, have been recognised.—Revision of Australian Lepidoptera, by Dr. A. Jefferis **Turner**. Under the above heading the author hopes to publish a series of papers dealing with the different families as time and opportunity permit. This first instalment treats of the Notodontidæ and Hyponomeutidæ.

DIARY OF SOCIETIES.

THURSDAY, MAY 21.

ROYAL INSTITUTION, at 5.—Proteid-Digestion in Plants: Prof. S. H. Vines, F.R.S.

THURSDAY, MAY 28, 1903.

THE ERUPTIONS OF MONT PELÉE.

Mont Pelée and the Tragedy of Martinique. By Angelo Heilprin. Pp. xiii + 335. (Philadelphia and London: J. B. Lippincott Company.) Price 15*s.* net.

THERE have been not a few greater catastrophes than that in which the city of St. Pierre was annihilated, and all its inhabitants (with only one or two exceptions) killed in a few minutes, but the peculiar circumstances of that tragedy have combined to bestow on it a great amount of interest. The city was one of the fairest in the western hemisphere, and no less famous for its profligacy than for its beauty. The suddenness with which it was destroyed, the awful circumstances with which this was attended, and the strange and almost unprecedented nature of the calamity have all combined to lend it a peculiar horror. At first the newspapers were filled with lurid and incoherent accounts of what had taken place, and all manner of exaggerations regarding the condition of Martinique were mingled with the most gloomy forebodings regarding the future of the island. In course of time a more rational spirit prevailed, but it is perhaps even yet too soon to expect a calm and entirely scientific study of all the remarkable features of the catastrophe.

Meanwhile the facts are being carefully sifted by various scientific men, and to the brief reports already published by Prof. R. T. Hill, Mr. E. O. Hovey, and the Commissioners of the French Academy of Science, this most interesting volume by Prof. Heilprin is a very welcome addition. In many ways the author of this book combines the qualifications necessary for successful treatment of the subject. He is an eminent naturalist, a much travelled geographer, and to his scientific knowledge he adds a dauntless courage which has enabled him to face calmly all the dangers of the dreaded volcano of Martinique. The book, moreover, is written in a style so graphic and vigorous that the reader is carried along in breathless interest, and no one who can enjoy a thrilling tale of adventure, however little he may be interested in scientific theories about volcanoes, could possibly put it down until he had reached the concluding page. The photographic illustrations are excellent. Many of them have been taken from Prof. Heilprin's negatives; others are from other sources, and have already appeared in the newspapers.

To those who have followed carefully the history of the eruptions, there is a great deal in the book that is not new. Much of it has appeared already in magazine articles by Prof. Heilprin and other writers, but even when following a well-worn path, the author is never dull, and his *résumé* of the earlier accounts is valuable, if only because he was one of the first scientific men to reach the island after the tragedy, and had in consequence special facilities for sifting the evidence before that rank growth of misstatement and exaggeration, which rapidly sprang up, had time to reach its full development. This, however, is merely the prelude to his tale, and the interest deepens when he describes the efforts he made to obtain a view of the crater near the summit of the mountain, and to study the processes at work there. He was the first to reach the actual summit after the tragedy of May, 1902, but luck was against him, and the mountain was veiled in mist; next day he returned, but still was unable to make out the details of the interior of the crater. In this he was not more unfortunate than other observers; we met a newspaper correspondent in Fort de France last year who had been five times on the top of Montagne Pelée, and had failed to secure a single photograph that would bear reproduction. As a matter of fact, those who would learn the condition of the crater should refer to the descriptions by Mr. Hovey and Prof. Lacroix, whose accounts are much clearer than those given in the book before us.

Though baffled, he was not defeated, and in the month of August Prof. Heilprin returned to Martinique to renew his investigations. He again ascended the mountain from its eastern base, and this time it is clear that he had a very narrow escape with his life. The volcano was very active, and was emitting a vast cloud of dust and casting great bombs for hundreds of yards from the crater. The descriptions of the scenes on the upper part of the volcanic cone are vivid, and to those who know with what suddenness the deadly black cloud can rise from the crater and sweep down the mountain slopes to the sea, it is evident that the party carried their lives in their hands. Not much information of scientific value was likely to be obtained in the circumstances, for it was impossible to approach sufficiently near the crater to see what was going on there. Prof. Lacroix has subsequently ascertained that what was at first regarded as an interior cone of ash is really a solid pillar of lava rising up from the bottom of the crater until it overtops the former summit of the mountain. The lava of Montagne Pelée, in fact, is so viscous and so nearly consolidated that it is being forced out as ice or lead can be forced through a narrow orifice under great pressure. So long as it is in its present condition it cannot possibly flow over the ground, and when the steam within it expands the mass is in large part shivered into dust.

The second fatal eruption of Pelée, that in which the village of Morne Rouge was destroyed and 2000 lives were lost, took place when Prof. Heilprin was residing on the mountain. His narrative of the events is wonderfully graphic, and though the fatal cloud was discharged at night, and in the darkness it was not possible to see exactly what happened, it is quite certain that the eruption was of the same type as that in which St. Pierre was levelled with the ground. Next day Prof. Heilprin visited the scene of the disaster and interviewed the survivors. Their experiences seem to have been very similar to those of the inhabitants of the Carib country of St. Vincent during the great eruption of May 7. The chapters of this book in which the story of this eruption is recorded are a very valuable contribution to the scientific history of the activity of Montagne Pelée.

The concluding chapter, in which the phenomena of the eruption are discussed, is in some ways not the least interesting in the book. From it we learn that

the author has discarded his bizarre hypothesis that the black cloud consists of "carbon gases" produced by the distillation of beds of asphalt in Tertiary deposits beneath the volcano. He is now of the same opinion as other scientific men, viz., that the main constituents of the cloud were steam, hot dust and sulphurous acid. We can hardly pass without remark his extraordinary calculations of the amount of dust ejected by Montagne Pelée during the latter part of 1902. He arrives at the conclusion that 480 millions of cubic feet of solid sediment have been discharged every hour, and is inclined to believe that this is an under-estimate. So far at least as regards that period when we were in Martinique in July, this is a wild exaggeration. For hours at a time the volcano emitted hardly a puff of steam; a casual visitor might never have suspected that the deep gully near the summit led into the crater; the amount of dust discharged was negligible. Yet this was the period immediately preceding and immediately following the eruption of July 9, which was one of the most important eruptions of last summer. When Prof. Heilprin adds, "We ask ourselves the questions—What becomes of the void that is formed in the interior? What form of new catastrophe does it invite?" we seem to hear the echo of the dire predictions which resounded in the colonial journals about twelve months ago.

JOHN S. FLETT.

EXPERIMENTS ON ANIMALS.

Experiments on Animals. By Stephen Paget. Pp. xvi+387. New and revised edition. (London: Murray, 1903.) Price 6s.

A BOOK which reaches a second edition in two years can do so only in response to some distinct demand, and such a demand is in itself no little recommendation as to its merits. The author of the book, Mr. Stephen Paget, was for twelve years secretary to the Association for the Advancement of Medicine by Research, and it was therefore his business "to know something about experiments on animals, and to follow the working of the (Vivisection) Act of 1876." He is therefore to a peculiar degree competent to write a book dealing with these subjects, and it is a matter for congratulation that the council of the Association above mentioned decided that the book should be written with a view to general reading. Though in this present edition all references to anti-vivisection societies and their methods are very wisely omitted, yet the obvious purpose of the book is to combat the misleading statements which these societies have disseminated broadcast amongst the uninstructed public, and to afford information concerning the results achieved by such experiments on animals, whereby the public may be enabled to judge for themselves as to the claims of the anti-vivisectors. To quote Lord Lister, who writes an introduction to this volume,

"The action of these well-meaning persons is based upon ignorance. They allow that man is permitted to inflict pain upon the lower animals when some substantial advantage is to be gained; but they deny that any good has ever resulted from the researches which they condemn."

Mr. Paget's object is therefore to convey to the general reader some idea of the inestimable advantages which have accrued to medical science from experimental research on animals. In the closing pages of the book, moreover, he points out that the vast majority of the experiments carried out at the present day in Great Britain involve no pain at all to the animals operated upon. The comparatively few animals subjected to painful experiment

"cannot be compared with the same number of horses, cattle, or sheep mutilated by breeders and farmers; for these mutilations are done, some of them, without any anæsthetic. They cannot be compared with the same number of pheasants or rabbits badly wounded, but not killed, in sport; for the animals thus wounded receive no subsequent care, and, if they are in pain, nobody puts them out of it."

To come to the actual contents of the book, we find that Mr. Paget devotes more than 200 pages to the consideration of experiments in bacteriology, but only 84 pages to experiments in physiology. It is to be regretted that the subject which forms the foundation of all medical science should be treated so cursorily, but in excuse it may be admitted that the practical importance of much physiological work is indirect, whilst that of bacteriological work is obvious and immediate.

In his account of experiments in physiology, Mr. Paget gives a concise *résumé* of certain chapters in the history of physiology. The circulation of the blood is treated rather more fully than other subjects, though Harvey's work receives but four pages of description and quotation. In the chapter on gastric juice, Mr. Paget very pertinently refers to the well-known case of Alexis St. Martin, in whom a permanent gastric fistula was produced by a gun-shot wound. Yet in spite of the numerous experiments made upon this man by Dr. Beaumont, no pain was experienced. Presumably, therefore, artificially produced fistulæ in animals are equally painless. In the chapter upon the nervous system, the important results obtained by Galen are described, and it is pointed out that the men who followed after him, though they worshipped his name, missed the whole meaning of his work through their neglect of the experimental method which he employed.

In his pathological chapters Mr. Paget gives a brief account of inflammation and suppuration, and then passes on to serum therapeutics. As the book is admittedly for general readers, it is a pity that no general introduction to this subject is given. The meaning of antitoxins and their method of preparation are nowhere described. The various chapters adduce a very copious body of facts as to the cure of diseases by serum-therapy and preventive inoculation, but the absolute necessity for experiments on animals, not only for the discovery and elucidation of the curative and preventive methods, but for the direct derivation of the immunising sera, is implied rather than clearly stated in so many words. In fact, it looks

rather as if the author had for the time being forgotten the primary object of his book, and had become so carried away by the intrinsic interest of his subject as to be oblivious to the fact that most of his readers must be entirely ignorant of the rudiments of preventive medicine. With this slight criticism we may pass on to enumerate some of the contents of this section. After chapters on anthrax and tubercle comes a very long one on diphtheria, in which an almost unnecessarily full list of statistics is given. In the chapter on rabies we have an admirable description of Pasteur's discovery and method of preparation of rabies virus. The cholera chapter is no less interesting. The plague chapter gives a detailed and most instructive account of the report of the Indian Plague Commission. Judging from the evidence adduced, this report seems unduly pessimistic, and one would have thought the commissioners entitled to go beyond their finding that "the method of serum-therapy is in plague, as in other infectious diseases, the only method which holds forth a prospect of ultimate success." In the typhoid chapter we are interested to learn that of the 12,234 officers and men forming the military garrison in the siege of Ladysmith, 1705 were inoculated against typhoid fever, and that amongst these the proportion of typhoid cases was only 1 in 48.7, whilst amongst the uninoculated it was 1 in 7.07. Still, there is nothing to indicate whether the inoculated were a fair sample of both men and officers, or were chiefly composed of the latter. The intensely interesting chapter on malaria and yellow fever gives an admirable epitome of the most important work done and results achieved in the elucidation of the cause and prevention of these diseases, and should be read by everyone who is compelled by circumstance to live near fever-haunted spots. Still other chapters deal with myxœdema, the action of drugs, and snake-venom, whilst the book closes with an account of the Vivisection Act and inspectors' reports.

H. M. V.

CHEMICAL TESTS AND THEIR DISCOVERERS.

Tests and Reagents, Chemical and Microscopical, known by their Authors' Names. Compiled by Alfred I. Cohn. Pp. iii+383. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 3 dollars.

THE appearance of this volume reminds one of two opposite tendencies that are developing in the terminology of modern chemistry. On the one hand, and more particularly in the "organic" division of the science, the chemist nowadays eschews all trivial or popular terms for his compounds, and strives to find appellations for them which shall be not merely names to remember the substances by, but titles which, at least to the initiated, are more or less self-explanatory. This is very meet and proper, and indeed some such system is probably unavoidable. But the union of the titular with the descriptive, *mariage de convenance* as it is, often produces some very ungainly offspring. Under the writer's eye there lies a recent volume of the *Journal* of the Chemical Society, several pages of which are plentifully besprinkled with such "names" as Ethylbromoketohydroxydihydropentanthrenedicarboxylate, and this is by no means the worst example that could be cited. Mark Twain once remarked of certain German polysyllabic achievements that they were "not words, but alphabetical processions." Similarly one may say of productions like the one above quoted that they are not names, but descriptive sentences with the verbs left out.

On the other hand, the instinct for brevity—combined sometimes, perhaps, with a suggestion of hero-worship or a tinge of Chauvinism—has simultaneously asserted itself in the upgrowth of a kind of personal nomenclature for numerous things chemical and matters microscopical. We have A's test and B's process; C's reagent and D's reaction; E's "number" and F's "value"; G's theory and H's "law"; every month sees additions to the list; and of the making of these minor immortals there seems no end. Time was when the cognominal designation was a distinct convenience. Perhaps it is so still, but in proportion as the number of such titles increases their utility diminishes, and if the hyphenless monstrosities of organic chemistry are sometimes almost undecipherable from their length, the proper names have become confusing by their multiplicity.

These now need, in fact, a dictionary to themselves. So far as tests and reagents are concerned, such an aid is furnished by the present volume. It gives in alphabetical order many hundreds of proper names by which various chemicals and operations are more or less generally known, and after each name describes, usually in a few words, the essential features of the test or reagent with which the name is associated. Most of the matter has already been published serially by the compiler in Merck's Report, and the amplified instalments are now collected in a single volume, where they will be found very convenient for reference.

What chiefly strikes one on looking through the book is that its value would have been much enhanced by the inclusion of more references to original descriptions, of which, indeed, only a very few are actually given. The increased space required would, surely, have been amply compensated by the greater utility secured. On account of the condensed style in which the descriptions are generally written, they are apt to be sometimes obscure; indeed, their chief value in many cases is that of a reminder to one who is already more or less familiar with the operation described. A person who had never previously performed the experiments would often want more detail, but as to where he could obtain it the author gives him no inkling. Nevertheless, the book will be of service to the busy chemist or microscopist. It does not claim to be a complete record, but there is a good deal of information given, and it appears to be generally accurate in substance if sometimes awkward in expression.

An index of subjects closes the volume, and is rather a curiosity in its way, since the body of it is made up almost entirely of proper names. The book may well find a place with the compiler's "Indicators" on the shelves of the chemical laboratory, and will be found useful in the microscopist's workroom.

C. SIMMONDS.

OUR BOOK SHELF.

Dictionary of Philosophy and Psychology. Vol. ii. Edited by J. M. Baldwin. Pp. xvi+892. (London: Macmillan and Co., Ltd., 1902.) Price 21*s.* net.

THIS, the second of the three volumes of Prof. Baldwin's dictionary, completes the text, for the third volume is to consist wholly of bibliographies. As in the case of the first volume, many of the articles are of high merit, but the standard of achievement varies pretty widely. The editor has taken a very liberal view of the range of subjects that call for notice, with the result that the ground is very completely covered, and place is given to a considerable number of topics in physical and biological science which a generation ago would hardly have been mentioned in a dictionary of philosophy or psychology. Perhaps the most valuable articles are those written by Dr. Stout and Prof. Baldwin conjointly, and forming a fairly complete series of careful definitions of psychological terms. We should like to have seen recognised the claims of psychology to rank as an independent science, freed from its ancient bondage to metaphysical philosophy, and if all that pertains to psychology had been brought together in a separate volume it would have formed a more useful, because more manageable, work of reference for the psychologist. The treatment of some topics suffers through being distributed under many separate headings, *e.g.* social science is treated of under that heading, but also under social dynamics, social evolution, social philosophy, sociology, social ethics, &c. Other subjects, again, suffer through being treated by too many hands, working not conjointly, but separately, and with imperfect coordination, so that we even find definitions begun by one writer or writers and finished by another, and in some cases conflicting views within the limits of one article. This is especially the case in the long article on vision. The biographical notes are unsatisfactory, because so very brief, and we note some slight inaccuracies, *e.g.* the description of G. H. Lewes as an English positivist, of R. H. Lotze as professor at Leipzig. These, however, are but small blemishes in a work that should be found very useful, not only by the philosopher and general reader, but by all students of psychology and the other biological sciences. It is interesting to note that "psychical research" receives formal recognition as a legitimate subject for study and research by the inclusion of several excellent articles from the pen of Mrs. Sidgwick.

How to Attract the Birds. By Neltje Blanchan. Pp. 244; illustrated. (London: W. Heinemann, 1903.) Price 5*s.* net.

WHETHER the author of this book should be addressed as Mr., Mrs., or Miss, and whether the name which appears on the title-page be real or assumed, we cannot determine, but we have little hesitation in saying that this and other works by the same pen have a charm and a freshness by no means apparent in all the bird-books which have come under our notice. Although written in America, and treating solely of American birds, the present work, like its predecessors, can scarcely fail to appeal to the English reader and bird-lover; and many of the hints given as to the best mode of attracting and keeping birds in gardens and plantations on the other side of the Atlantic will be equally applicable in the case of our native British species. On one point the author is very emphatic—namely, the impossibility of getting a large number of shy and attractive birds to frequent and build in a garden when a cat is also kept on the establishment. Not only are such attempts unsuccessful, but they are also cruel. In America, where garden crops and produce suffer perhaps even more damage from insects than is the case in this country, the small expenses connected with populating an estate with birds are more than compensated by the accruing advantages to fruit and flowers by the destruction of insect life.

"One pair of chickadees (whatever these may be) in an orchard," writes the author, "will destroy more insect eggs than the most expensive spraying machine." Apparently, indeed, the author will not allow that any bird can do harm in a garden; but then he (or she) has probably never seen a flock of bullfinches in a gooseberry plantation, or witnessed the mischievous devastation inflicted on a primrose-border by sparrows!

An attractive feature of the book is, of course, the numerous, and for the most part exquisite illustrations, more especially those of nests and eggs. In the case of some of the adult birds represented in foliage, we have a shrewd suspicion that they have been "faked up" by means of stuffed specimens, but even then the general effect is in most cases good. While devoting much attention to the proper subject of the book, the author by no means omits reference to the scientific aspects of ornithology, and the observations with regard to the white "recognition marks" on the loins of birds like our own wheatear are worthy of all attention. As a whole, Neltje Blanchan's latest work may be pronounced a charming and attractive volume.

R. L.

Telephone Lines. By W. C. Owen. Pp. xvi+390. (London: Whittaker and Co., 1903.) Price 5*s.*

THIS book deals in a thoroughly practical manner with the construction and erection of overhead telephone lines and the laying of underground cables. The author's long experience as a telephone engineer enables him to write with authority on the subject, which he treats in all its important engineering aspects, from the best methods of preserving the wood used for poles to the final electrical testing of the finished line. American and continental practice is described as well as British methods. Telephony has always been regarded as a branch of applied science in which this country can by no means claim to be to the fore; the perusal of Mr. Owen's book certainly lends support to this belief, as the examples of continental methods which are quoted show in many instances considerable superiority. The theoretical explanations which are here and there required to show the necessity of certain methods of construction are expressed in clear and non-technical language well suited to linesmen and others who are not technical experts, for whom the book is largely written. A large number of illustrations help to explain the text; the book should prove very useful to those engaged in, or having anything to do with, telephone work, and may, moreover, be read with interest by all who care about the practical applications of science.

M. S.

The Globe Geography Readers. Intermediate. Our Island Home. By Vincent T. Murché. Pp. 293. (London: Macmillan and Co., Ltd., 1903.) Price 1*s.* 6*d.*

IN the introductory and junior readers belonging to this series, already noticed in these columns, the young pupil is provided with simple explanations of the general principles underlying the study of geography; the present volume deals specifically with the physical and political geography of the United Kingdom in fifty-six short lessons, the subject-matter of which is varied and discursive, ranging from an account of the prehistoric inhabitants of Britain to a description of Irish scenery. The lessons are written in an interesting, conversational style, and are accompanied by an abundance of instructive illustrations, including sixteen coloured plates.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Psychophysical Interaction.

I MUST demur to the statement of my views which Sir O. Lodge has given in his letter printed in NATURE for May 14, "that if dynamical laws are exact and irrefutable, the universe must be a completely determined mechanical system, with only one, and that a necessary, solution." In the first place, I made no statement as to the universe as a whole; as I do not know the physical universe to be finite in extent, I prefer to make statements only about finite portions of the universe, and the interactions of such finite portions. I certainly hold the view that the laws of dynamics, which are a self-consistent system of formal laws, are exact and irrefutable, but the question whether the motions of all parts of a living organism are in accordance with those laws is quite another matter, and one on which I have expressed no opinion. What I did in effect say, was that a material system upon which forces of psychical origin and of incalculable magnitude acted, traversed the laws of dynamics in the only sense in which such a system of laws can be traversed, viz. that the motions would not be in accordance with the laws, whether the supposititious forces do mechanical work or not.

Sir O. Lodge maintains that the psychical and the physical can interact without upsetting any fundamental dynamical law; he objects to the principle of Least Action as containing assumptions which beg the question at issue, and pins his faith to Newton's laws. Now, although the principle of Least Action contains nothing which is not deducible from Newton's laws, provided the same form of energy-function is taken in the two cases, I will, for the sake of argument, accept the test that Sir O. Lodge lays down. One of Newton's laws is that to every action there is always an equal and opposite reaction, or every stress has two aspects; now I suggest for Sir O. Lodge's consideration the following questions:—What are the reactions corresponding to the forces of psychical origin which act upon parts of a living organism? On what do such reactions act? It will clearly not suffice to say that the reactions are something of a different character from the actions, and are appropriate to exert an influence upon the psychical; Newton's reactions are mechanical forces acting upon material systems.

As an example of a mechanical system the motions of the parts of which are determinate through the laws of dynamics in conjunction with the law of gravitation, we may take the solar system, supposing each member of it to be treated as a whole. Let us suppose that there resided in the solar system some agency of a non-material character which was capable of applying to the planets forces of unknown magnitudes along the normals to their orbits relative to the centre of gravity of the system. The paths of the planets could then no longer be calculated; in fact, there would be an end of gravitational astronomy; both the linear and angular momenta of the system, so far from being conserved, would become absolutely indeterminate, and yet Sir O. Lodge must in consistency maintain that the laws of dynamics would not be traversed. Moreover, although the sum of the potential energy and the kinetic energy of the motions relative to the centre of gravity would be unaltered, the energy of the motion of the whole system through space would be altered to an unknown extent. If the disturbing forces acted normally to the paths relative to a point regarded as a fixed origin for the sun and stars, the energy of the system would be conserved, but in all other respects the same result as before would ensue, namely, chaos.

There are, I take it, in the main three views which may be maintained as regards the relations of the psychical and the physical in living organisms.

(1) The view known as pure naturalism, that the physical forms an independent system, and the psychical is only a *Begleiterscheinung* influenced by, or perhaps determined by, the physical, but exerting no influence on the physical. In this case the motions of the physical are entirely determinate in accordance with mechanical laws.

(2) The view that the psychical and the physical form two systems linked together, with interaction between the two; on this view neither system is complete in itself, and the physical cannot be determined completely by any system of purely mechanical laws. This view does not exclude pure determinism as regards the whole complex, since it may be held that the psychical has a dynamics of its own, and that the interaction between the psychical and physical is determinate in accordance with some scheme of laws.

(3) Lastly, it may be held that the dualism of the physical and psychical is entirely inadequate as an ultimate formulation; in fact, that both (1) and (2) are unworkable as thorough-going hypotheses; on this monistic view, both the physical and the psychical must be regarded as manifestations of something more fundamental than either. This view, as also (2), does not exclude the partial and tentative application of mechanical laws, even to the case of living organisms; there may be a partial or practical independence of the physical in certain classes or cases, but such practical independence could never be presumed apart from proof of its existence by means of actual observation, and there must certainly be a point at which the practical independence breaks down, and at which the dualism of our ordinary mode of thinking becomes inadequate as a representation of what happens. It is this last view of the matter which I am inclined, personally, to regard as the true one.

E. W. HOBSON.

Christ's College, Cambridge, May 17.

WITH the help of one of Clerk Maxwell's demons a very simple illustration of change of motion in a dynamical system, without any interference with the sums of energy and momentum, can be constructed, which may perhaps be of service to Mr. McDougall.

Let the demon provide himself with some inextensible, perfectly flexible, mass-less string. (It is found abundantly in text-books of Dynamics.) Let him observe two bodies of the system, having, it may be, motions of rotation as well as of translation; and when he discovers a point on each the relative velocity of which with respect to the other point is either zero or at right angles to the straight line between them, and which also are about to recede from each other, let him, at the very instant when things are so, attach a piece of his string to these two points exactly equal in length to the distance between them. The two bodies will thus be suddenly yoked together without any shock whatever, and consequently without any loss of energy. Their subsequent motions of translation and rotation will be altered by the action of the string; but their total energy and their total momentum will remain entirely unaltered. As soon as the string slacks the demon must be careful to remove it, in order to avoid the possible shock when it again tightens.

If the string be perfectly elastic (so that no energy is dissipated in internal work when the string stretches) instead of inextensible, the demon may attach it to any two points on the surfaces of the bodies without affecting the momentum sum or the energy sum; but so long as the string is at all stretched, a portion of the energy of the two bodies will be stored up in it.

For example, let the two bodies be spheres moving with the same uniform, rectilineal, velocity; and suppose the centre of figure of each to be its centre of inertia. Let each be spinning about an axis through its centre, perpendicular to the plane in which the centres are moving. Then the demon may safely fasten his inextensible string to the two points where the straight line joining the centres cuts the surfaces. There will be no shock, and therefore no loss of energy. There will be also no change in the total momentum of the spheres, whether linear or angular, nor any change in the uniform, rectilineal, motion of their common centre of inertia; nevertheless, when the demon releases them, they may be moving in divergent instead of parallel directions, and with diminished or increased velocities of rotation.

Demoniacal guidance of this kind conflicts neither with the law of conservation of energy nor with that of the conservation of momentum, and so far would seem to contradict Prof. Ward's criticism in his "Naturalism and Agnosticism," vol. ii. p. 83.

J. W. SHARPE.

Woodroffe, Bournemouth.

PROF. MINCHIN raises the question of the desirability, or undesirability, of the use of adjectives with regard to physical principles. If the noun deserve the adjective, and if the meaning of the adjective be clear, it is not easy to see why the word should be omitted. Prof. Tait is cited, rather unfortunately, as the leader of those who apply the word "grand' to the principle of conservation of energy, while refraining from its application to certain other physical principles. Whether or not it be the case that "following his lead, all but the most sober mathematicians use the laudatory adjective when they write about this particular physical principle," it is certain that all but the least sober physicists will see a very real reason for the use of the term—precisely the reason which led Tait to adopt it.

Prof. Tait's use of adjectives is instructive. He made a very characteristic use of the term "mere," a word which Prof. Minchin would abolish along with "grand." He spoke of the mere mathematician, that is, a mathematical machine not possessed by the soul of a physicist.

But Tait did not refuse glorification to the principle of conservation of matter. He placed it, in that respect, on the same high level as the principle of conservation of energy. And he glorified Newton's laws, so glorifying the principle of conservation of momentum and the other principles alluded to by Prof. Minchin.

Tait also knew that it was possible so to state the principle of conservation of energy in a dynamical system as to make it include that of conservation of momentum. This was pointed out in an early chapter of a text-book on dynamics which he never completed.

Assume an origin and axes of reference. Let the (conserved) energy of a system be E_1, so that

$$\Sigma(mv^2) = 2E_1.$$

Assume that the energy is also constant ($=E_2$) when the motions are referred to an origin moving uniformly with speed a_2 in a direction making an angle θ with the line of motion of the mass m, and we get

$$a_2^2\Sigma(m) - 2a_2\Sigma(mv\cos\theta) = 2(E_2 - E_1).$$

Similarly

$$a_3^2\Sigma(m) - 2a_3\Sigma(mv\cos\theta) = 2(E_3 - E_2)$$

if we refer to an origin moving with uniform speed a_3 in the same direction. Hence

$$\Sigma(\dot{m}) = 0. \quad \frac{\partial}{\partial t}\Sigma(mv\cos\theta) = 0.$$

The latter equation asserts conservation of momentum, the former asserts conservation of matter.

In the same way, if we postulate that momentum, found to be conserved when referred to certain axes and a given origin, is also conserved when referred to an origin moving uniformly with regard to this reference system, we can deduce the principle of conservation of matter.

It is impossible that all three—matter, momentum, and energy—can be in general found to be conserved simultaneously when referred to an origin in varying motion. If matter be conserved, and if we could measure, from our standpoint on the earth, the momentum and energy of the universe, we should find one or both to be subject to at least yearly, monthly, daily, &c., periodic variations. If the origin move with the centre of inertia, as in all cases directly experimented upon, all three principles hold if two hold, while the energy is found to be constant in at least one state of motion of the centre of inertia, say zero. The discussion of absolute conservation is as futile as the discussion of absolute motion.

It may be that energy, or momentum, is only conserved on the average as to space and time, the departures being on an ultra-measurable scale and yet sufficient to account for "guidance" action in living beings. But we do not require to postulate this in order to account for guidance action. Such action might occur and yet be in accordance with conservation of both momentum and energy. Maxwell's demons could bring it about. Suppose that the mass of a demon is zero, that he is perfectly elastic, and that his parts are capable of rapid relative motion. Let an army of such demons receive orders to abstract heat from one portion of a body and give it to an adjacent portion, so as to establish a difference of temperature while keeping the total energy constant. Because of his zero mass, each demon must adjust himself, in acting upon molecules, so as to produce zero change of momentum at any instant. He can allow quickly moving molecules to pass in one direction, slowly moving molecules in the other, while he prevents to some extent the reverse process. He might thus work railway points with no expenditure of energy on the whole, and with no change of momentum on the whole. The only principle temporarily interfered with is the principle of dissipation of energy; and that is temporarily interfered with constantly in nature.

Such speculations are of no value except as showing that guidance action *may* occur without overthrowing accepted dynamical principles. Further discussion lies outside physics. As Tait said, "human science has its limits, and there are realities with which it is altogether incompetent to deal." A sufficiently wide Monism is scientific and good.

W. PEDDIE.

University, Edinburgh.

IN his letter on the conservation of energy (p. 31), Prof. Minchin holds that, while energy might be conserved in the physical universe acted on in some way by mind, yet neither force nor momentum would be. "They" (the causes altering the configuration of a system) "infallibly alter its total momentum and total force in every direction."

Even for changes produced by physical causes, *e.g.* the pressure of a smooth rail, this may not be the case. It is true the rail will not guide a moving body along it unless it exerts pressure, and then it will generally alter the momentum of the system, to which the rail itself is not supposed to belong. It may happen, however, that the pressure from without is exerted in equal amount in opposite directions. Further, if it were true that the total momentum would be infallibly altered by a *physical* cause, this would prove nothing for psychophysical action, unless we beg the whole question, and assume at the outset that the motion of matter can only be affected by what is material.

The constant use of physical analogy in this connection soon leads to obscurity. The only resemblance that can at present be said to exist between the action of mind and that of an ideal immovable rail is that both do no work. To explain *how* mind acts on matter, such analogies are useless. At most, in the case under discussion, they can only serve to show that there are possible causes of change which do not affect the energy. It is only, I think, an undue use of physical analogy—the action of the mind, for instance, being thought of as pressure—that can prompt the statement that any cause of change must alter the total momentum in some direction.

The laws of mechanics are merely regulative, and are not of themselves sufficient to account for the motion of a dynamical system with given initial conditions, unless it is stipulated that all action is mechanical, or at least unless the action on, or interference with, the motion is exactly defined. This is proved by the simple fact that we can solve examples in dynamics in which we suppose arbitrary, known interference to take place. In such examples, as a rule, the momentum of the system would be altered, but that is not at all necessary.

In conclusion, then, it may be agreed that the action of mind does not violate the laws of mechanics, but that no more prevents mind producing changes than it prevents those produced by ordinary mechanical action.

Extension of Kelvin's Thermoelectric Theory.

LORD KELVIN'S thermoelectric theory has always seemed to me to be one of his best works. Since its enunciation the scope of the electric current has been extended, as in Maxwell's theory. It is now the curl of the magnetic force of the field always and everywhere. A corresponding extension of the thermoelectric theory is needed. I do not know whether it has been done, but it may be shortly stated, and contains some striking results. As regards the necessity, the following case will show it plainly. Make up a circuit of two parallel wires of different materials, both thermoelectrically neutral, say one of lead, the other of one of Tait's alloys. The places of thermoelectric force in the circuit are then the terminals. Now send short waves along the circuit, in the way so often done of late years. There need be no current at all in the circuit at one end to pair with that at

the other. So there is complete failure of the theory of metallic circuits.

But the needed extension is easily made by following Lord Kelvin's method, and using the enlarged meaning of electric current. Let **e** be the intrinsic voltage per unit length due to reversible thermal action, and let **C** be the current density. Then **eC** is the heat per unit volume absorbed per second, and the second thermodynamic law requires that $\Sigma \mathbf{eC}/\theta = 0$, if θ is temperature, the summation to be complete as regards **e**. Here **C** may be any circuital current, so $\mathbf{e}/\theta$ is polar; that is, $\mathbf{e} = -\theta\nabla p$, where p is a scalar, the thermoelectric power. In a homogeneous conductor, p is a function of the temperature only, to suit Magnus's results. But it is also a function of the material. In what way is not known, but it shows itself at the junction of different metals. Then p changes, say, from p_1 to p_2, so the intrinsic voltage at the junction is $P_{12} = \theta(p_1 - p_2)$. This is the Peltier force from the first to the second metal. So far is all that is necessary for steady currents. But when the current varies, part of it leaves the metals. Now at a metal-air junction, the thermoelectric power falls from p to 0, so there is an additional thermoelectric force $P\mathbf{N}$ or $p\theta\mathbf{N}$ acting outwards, **N** being the unit normal. It is here assumed that the thermoelectric power of air is zero. It does not seem likely that its value is important compared with p in a metal. This $P\mathbf{N}$ multiplied by the current leaving the conductor measures the reversible thermal effect at the boundary. The system is now complete, provided there is no external **e**. But should there be, then it must be counted too, if, for instance, a current is induced in an external conductor. In any case, $\mathbf{e} = -\theta\nabla p$ will be valid, with the usual proper interpretation of discontinuities, and the Maxwellian meaning of the current.

It will be sufficient to suppose that $p = 0$ outside a circuit of two metals. Then there is the Thomson force in the metals, the Peltier force at the metal junctions, and the metal-air force $P\mathbf{N}$ of variable intensity all over the circuit. In the extreme case with which I commenced, there may be only one Peltier force in operation, or even none at all, but just the metal-air force alone. If so, there is reversible evolution of heat at some parts, and absorption at other parts of the boundary.

As regards the application of the second thermodynamic law, it seems to be justified by experimental results with steady currents. I see no reason why it should not be applied to variable currents, even when varying very rapidly. For p is a property of the material and its temperature at any place, and has nothing to do at the moment with what is going on at other places. Yet a reservation is necessary. For the second law results from averages. So there must be some limit to the rapidity with which the current at any spot may vary, if the second law is to be fully valid there.

The Volta contact force must not be forgotten in connection with the metal-air thermoelectric force. Mr. J. Brown has lately made the Volta force disappear by heating it away in oil. If this is fully confirmed, it perhaps proves that chemical action between the metal and an electrolytic film of moisture is the real source of the energy of the transient Volta current, as Mr. Brown maintains. How will this affect the thermal force? If we allow properly for the change in p in passing through the film from the metal to the air, it seems likely that the thermoelectric effects will be simply superposed upon the Volta effects, because the sources of energy are different. Yet they might have to be combined in some unknown way.

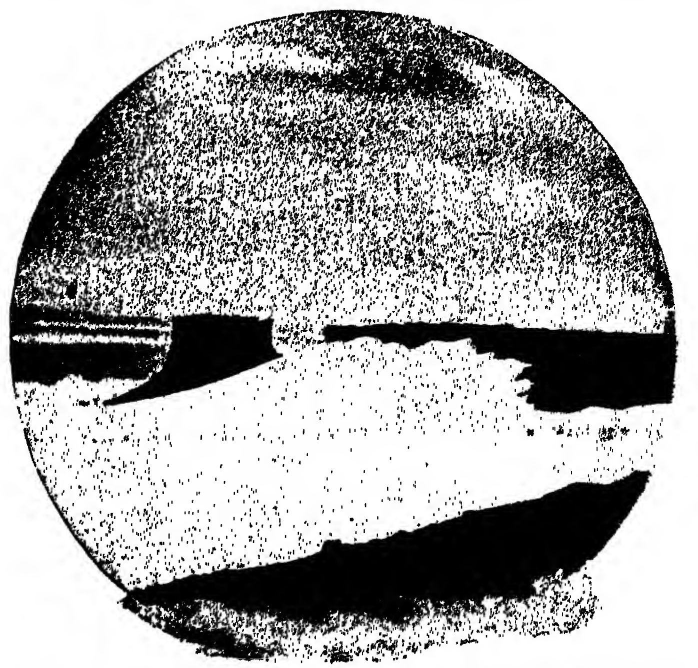
Returning to the steady current in a circuit of two metals, Lord Kelvin showed that the complete intrinsic voltage amounted to $\Sigma p d\theta$. This does not express the real distribution of intrinsic force in the circuit, and seems to have no meaning. But it has a curious interpretation, which is of importance in the extended theory. The necessity of the metal-air force is shown in another way. I have shown that the source of **H** in varying states is the curl of **e** everywhere. Here this is $\mathbf{f} = \mathrm{V}\nabla p\nabla\theta$. It is zero in a homogeneous conductor, and also at the metal junctions, but has the boundary value $\mathrm{V}\mathbf{N}\theta\nabla p$, which would represent the source of **H** if there were no metal-air force. But add on the curl of the metal-air force $P\mathbf{N}$ or $p\theta\mathbf{N}$. It is $-\mathrm{V}\mathbf{N}\nabla P$, and the sum of the two is $-\mathrm{V}\mathbf{N}p\nabla\theta$. Now this is also the curl of the fictitious intrinsic force referred to, that is, $p\nabla\theta$ in the metals only. So we come to this striking result, that Lord Kelvin's $\Sigma p d\theta$ in the metal circuit alone is a fictitious distribution which not only gives the same steady current as the real distribution of intrinsic force, but also gives the true **E** and **H** everywhere in variable states as well, provided the real intrinsic forces include the metal-air forces along with the Peltier and Thomson forces.

OLIVER HEAVISIDE.

May 18.

THE FARTHEST NORTH.

H.R.H. Prince Luigi Amedeo of Savoy, Duke of the Abruzzi, has given to the English-reading public a superb account of his great Arctic expedition.[1] Though he has fortunately adopted a smaller size of volume than his Imperial namesake, the Archduke Ludwig Salvator, devotes to his luxurious memoirs on Mediterranean islands, the book is still both ponderous and imposing. Although in octavo, it is as large as most quartos, and it is a credit to the publishers in every way. A royal opulence is reflected from the burnished pages, which reflect the light also so perfectly that at night it is impossible, without elaborate precautions, to prevent the image of the lamp-flame from concealing part of the text. The very fine half-tone reproductions of photographs with which the book is crammed profit by the quality of the paper. The portraits of Admiral Markham and Dr. Nansen, illustrating the introduction, are not, however, very happily chosen, and we miss a satisfactory portrait of Captain Cagni, the hero of the memorable journey to the farthest north.



IG. 1.—Cape Säulen, seen from the south-east. (From "On the *Polar Star* in the Arctic Sea.")

The royal author writes modestly and well, his

1 "On the *Polar Star* in the Arctic Sea." By His Royal Highness Luigi Amedeo of Savoy, Duke of the Abruzzi, with the Statements of Commander U. Cagni upon the Sledge Expedition to 86° 34′ N., and of Dr. A. Cavalli Molinelli upon his Return to the Bay of Teplitz. Translated by William Le Queux. In two vols.; with 212 illustrations in the text, 16 full-page photogravure plates, 2 panoramas and 5 maps. Pp. 702 + xxii + xii. (London: Hutchinson and Co., 190)

narrative occupying the first volume, and serving to show that he was a good comrade and a brave explorer, sharing all the discomforts of a somewhat miserable wintering without complaint. The translation, too, is well done, running so smoothly that it is rarely recognisable as a translation at all. Now and again, however, little bits of awkwardness come to light. A medical man would hardly write in English of the "digestive tube," nor would a sailor refer to the "left side" or the "chimney" of a steamer—"it's no a lum, it's a funnel," said "Wee Macgreeger" scornfully on one occasion. Trifles of nomenclature also show the want of first-hand knowledge; where the form is so beautiful it jars one to run against a "Thompson" compass, a "Clement" Markham, or even an "Ommaney." We wonder whether the British public nowadays attaches any more definite meaning to a dram as a unit of weight than it does to a gramme; and we are sorry for the task set to poor Dr. Cavalli in weighing out 8oz. 13·0958dr. of tinned meat for each man every day; though we are reassured in finding that the metric units quoted alongside prescribe only the quarter of a kilogramme, and we presume that he did not trouble himself to weigh it to the fifth of a milligramme as the English version suggests. This habit of translating foreign units by some theoretical table is so common that it is really time to put in a plea for the exercise of common sense, which in this case would suggest 8¾oz. as a sufficient equivalent for 250 grammes, and in another would delete a residuum of 4 drams in a weight of nearly a ton.

FIG. 2.—The *Polar Star* after the Ice Pressure. (From "On the *Polar Star* in the Arctic Sea."

The narrative of the Italian expedition has already been summarised in NATURE (vol. lxiv., 1901, p. 158), and it need not be repeated. The first of the volumes before us supplies many additional particulars as to the first navigation of Queen Victoria Sea, and the long struggle with the ice before the *Stella Polare* reached the northern limit of the Franz Josef Land archipelago beyond Rudolf Island. It deals with all the usual incidents of a winter sojourn in high latitudes, made in this case unexpectedly hard by the party being obliged to leave the ship, which had been specially prepared for wintering in, and to camp instead in extemporised tents. There are few references to scientific work, but observations were made and collections obtained which are being discussed in a series of volumes by Italian specialists. Enough is said, however, to show that the observations must have been frequently interrupted. The difficulties of high wind and snowdrift proved much greater than were expected with regard to the meteorological instruments, in the management of which some preliminary experience at a high-level observatory in Europe would have been of great assistance. The magnetic hut, too, suffered from stress of weather; but we hope that the results obtained will yet prove of value.

Most interest naturally attaches to the second volume, which deals mainly with Captain Cagni's fine attempt to reach the Pole. This attempt proved more nearly successful than any sledging expedition before or since, and it is narrated by the captain himself. There is no doubt that if the commander of the expedition had sufficiently recovered from the serious frost-bite from which he suffered he would have led the advanced party to the farthest point. The pluck and endurance of the Duke of the Abruzzi have been amply proved, while the fact that when himself disabled he insisted none the less on his second in command carrying out the programme speaks volumes for his generosity and patriotism. The expedition was a private one, planned to gratify the laudable ambition of an illustrious personage, and no one could have reasonably objected if the commander had changed his plans and stopped the expedition when he found he could go no farther. Captain Cagni and the three Italian alpine guides who accompanied him were worthy of the confidence reposed in them, and they were rewarded by being able to carry the Italian flag a little nearer to the Pole than the flag of any other nation has yet been taken. Beyond observations of latitude, no scientific work was possible on this arduous journey; but the result showed clearly that, given a sufficiency of dogs, no piece of polar travel need prove too difficult for resolute men. The dogs of the *Stella Polare* not only drew the sledges, but, as in Nansen's case, they furnished a food-supply for their surviving comrades, and in this case towards the end for the explorers themselves. It is curious to find that the exhaustion of provisions, or even of the petroleum used for fuel, excited comparatively little interest so long as a few dogs were left to furnish

meat and grease to burn for cooking it; but the utmost anxiety was caused by the wearing out of the aluminium stove and cooking utensils. As regards clothing, the Italians found woollen material much more useful and satisfactory than furs. The point is discussed at some length by Dr. Cavalli, who observed that light porous cloth allowed the perspiration to pass to the outside before freezing, and there it could be scraped off and the clothes kept comparatively dry; whereas when skin clothing of any kind was used, snow and ice were formed on the inner surface, and when warmed in the sleeping-bag the clothes were saturated with moisture.

The Italian and Norwegian members of the expedition appear to have been on the best of terms throughout, and but for the loss of the first party returning from the great journey over the sea-ice, their year in the Arctic regions must be pronounced a most successful one. What is now wanted in the interest of science is no mere dash to the Pole, no more experiments as to modes of travelling, but a repetition of the drift of the *Fram* from a point north of Bering Strait, with abundant equipment for oceanographical, meteorological and magnetic research. It would cost but a trifle compared with the expense of an expedition with dogs and stores enough to ensure reaching a very high latitude from any land base, and the value of the results is certain, though five years might not be too much to allow for obtaining them. It is a great opportunity, ready for some wealthy person with a love of solitude and science.

THE RESTORATION OF THE LAND OF CHALDEA.

TWO lectures by Sir William Willcocks, late Director-General of the Irrigation Works in Egypt, delivered before the Khedival Geographical Society at Cairo, have been published in a pamphlet,[1] a copy of which has been received. Sir William Willcocks, as is well known, is an enthusiast in irrigation matters, and has had a very large share in bringing Egypt to its present state of prosperity by the reorganisation of the canal and reservoir system, and in designing the new works that have recently been carried out at Assuan. The pamphlet under notice relates to the ancient country of Chaldea, which bears a great resemblance in its physical features to Egypt, the river Tigris being capable of performing the same functions as the Nile.

In view of the proposed Bagdad Railway, which will traverse this delta, the subject is of considerable interest. The author's view is that the resuscitation of the ancient canal system would create along the line of railway a country as rich as Egypt, the rent of which would pay for both railway and irrigation works, and leave a surplus "which only those can realise who have been in intimate touch with Egyptian Agriculture."

Bagdad lies at a distance of about 500 miles from the sea, measured along its course. From the city to the Persian Gulf is a country now completely desolate, but which formerly was one of the most fertile and populous districts in the world. Opis, situated on the banks of the Tigris, and which was at one time the wealthiest mart of the East, bears to the delta of the Tigris very much the same relation that Cairo bears to the delta of the Nile; and here were situated the head of the great canals which irrigated the delta. The great Nahrwan canal had its intake in this locality, and extended for a length of about 250 miles, feeding an immense number of subsidiary canals. This canal, for the first ten miles of its course, was cut through hard conglomerate rock to a depth of 50 feet, and was 65 feet wide, increasing lower down to 394 feet. These dimensions considerably exceed those of the largest irrigation canal in Egypt. It was described as late as 970 A.D. as flowing amid continuous and extensive villages, date groves, and well-cultivated lands, the whole region over an area of 4600 square miles containing a population, judged from the ruins left, that no spot on the globe could excel. Owing to neglect of the works the main stream of the Tigris became diverted, the old bed of the river silted up, and the ruin of the irrigation system became complete, and now the ruins of Opis and many other mounds of adjacent buildings spread like islands over the deserted plain, which is quite bare of vegetation. The author of the pamphlet estimates that there are about one and a quarter million acres of first-class land of the value of 38,000,000*l.* that could be reclaimed and once more made prosperous by an outlay of 8,000,000*l.*, and which would produce a rental of 3,840,000*l.* Beyond this is an area of one and a half millions of acres of less fertile land, that could also be reclaimed and cultivated.

The second lecture is a description of what Egypt will be in fifty years' time, according to the author's ideas, when the country "will attain a height of splendour and magnificence." which will surpass the great works of the days of the Pharaohs, which have survived the revolutions and catastrophes of four thousand years.

[1] "The Restoration of the Ancient Irrigation Works of the Tigris; or, the Re-creation of Chaldea"; and "Egypt Fifty Years Hence." By Sir William Willcocks. Pp. 71; with 10 plates. (Cairo: National Printing Department, 1903.)

THE DALTON CELEBRATIONS AT MANCHESTER.

THE Manchester celebrations in connection with the centenary of Dalton's atomic theory began on Tuesday afternoon, May 19, when Prof. F. W. Clarke, chairman of the International Commission on Atomic Weights, delivered the "Wilde" lecture on "The Atomic Theory" to the Manchester Literary and Philosophical Society. Addresses were presented on behalf of the Royal Society and the Chemical Society, and a message was received from the Russian Physico-Chemical Society. In an admirable discourse Prof. Clarke sketched the history of the atomic theory from its first conception in the minds of Greek philosophers down to the present day. He pointed out the directions in which the atomic theory would probably develop, but declared that the problem of matter would never be solved until the atomic weights of the elements had been finally settled. "Who," he asked, "will establish the Dalton Laboratory for pure research, and so give the work which he started a permanent home?"

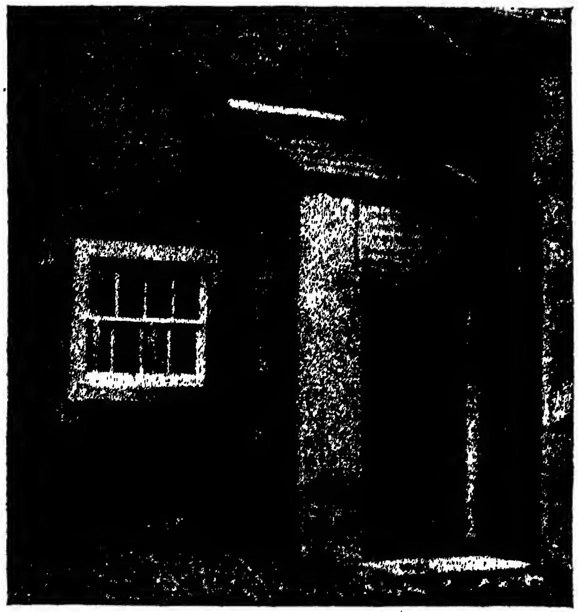
In the evening the Literary and Philosophical Society gave a dinner, at which the principal guests were Profs. Clarke and van 't Hoff, Prof. A. E. Armstrong, Mr. Brereton Baker, Prof. P. F. Frankland, Mr. Vernon Harcourt, Dr. Harden, Sir James Hoy, Prof. Kipping, Dr. W. H. Perkin, sen., Sir William Ramsay, Prof. Emerson Reynolds, Sir Henry Roscoe, Prof. Smithells, Dr. Scott, Prof. Thorpe and Prof. Tilden.

In proposing the toast of the evening, the "Wilde" medallist—Prof. Clarke—and the Dalton medallist—Prof. Osborne Reynolds—Sir Henry Roscoe said that Dalton's atomic theory and Joule's discovery of the mechanical equivalent of heat reflected more distinction on Manchester than the city's association with the cotton industry or with the Ship Canal.

On Wednesday morning a special meeting of the Owens College Chemical Society was held to offer an address to the great Dutch chemist, J. H. van 't Hoff, now professor at the Berlin University. Prof. Dixon

was in the chair. The address was presented by Mr. Norman Smith, a former student under Prof. van 't Hoff. The professor, who was enthusiastically received, said the question was often asked, nowadays, whether the atomic theory had not outlived its utility. His reply was that, in dealing with natural phenomena, with states of unstable equilibrium, the atomic theory was indispensable for essential explanations. He had come to regard the conception of the carbon atom as the centre of a tetrahedron as childish, but it contained the germ of a profound truth, the solution of which must be left to the future. He suggested that valency was due to an equilibrium. The four mutually repellent "electric atoms" of Helmholtz were kept in equilibrium by their attraction for the carbon atom at the centre.

Later in the morning Earl Spencer, Chancellor of the Victoria University, conferred the honorary degree of Doctor of Science on Prof. Clarke and Prof. van 't Hoff, who were presented by Prof. Dixon. After the conclusion of the ceremony Prof. van 't Hoff laid the



Memorial Tablet over door of house in which John Dalton was born. From a photograph supplied by Mr. A. Humphreys. The inscription on the tablet reads:—"John Dalton, D.C.L., LL.D., the Discoverer of The Atomic Theory, was born here Sept. 6, 1766. Died at Manchester July 27, 1844."

first stone of the proposed extension of the Owens College Chemical Laboratories, and was presented, as a memento of the occasion, with a silver trowel by the College Chemical Society. The celebrations were concluded by a soirée held at the Owens College on Thursday night, when Dr. Harden gave an interesting account of John Dalton, and many Dalton relics were exhibited by the Manchester Literary and Philosophical Society, Prof. H. B. Dixon, Mr. Theodore Neild, Mr. G. W. Graham and Mr. G. S. Woolley. E. C. E.

THE ATOMIC THEORY AND THE DEVELOPMENT OF MODERN CHEMISTRY.

MANCHESTER celebrated last week, just a little prematurely, the centenary of John Dalton's atomic theory. It was on September 6, 1803, that he drew up in his notebook his first table of weights of the "ultimate atoms" of hydrogen (which he took as his unit), oxygen, "azot," carbon, sulphur, and of water, ammonia, nitrous gas, nitrous oxide, and other binary compounds of these elements. With regard to the genesis of the theory in his own mind much doubt has prevailed until recently. Dalton himself told Thomas Thomson in 1804 that he had been led to the theory from his work on marsh gas and olefiant gas. He told W. C. Henry in 1824 that his speculations were suggested by the work of Richter. And yet, oddly enough, as Sir Henry Roscoe and Dr. Harden have shown in their "New View of Dalton's Atomic Theory" the evidence is dead against the accuracy of these plausible statements. Dalton's own notebook shows that his atomic theory preceded his work on marsh gas, and his notes for a lecture delivered in 1810 give a history of his ideas which agrees with all the facts.[1]

It was from Newton that Dalton derived his belief in the atomic hypothesis. And we can trace the "solid massy, hard, impenetrable, moveable particles" of Newton, through his friend Boyle, through Gassendi, and through Bacon (who considered Democritus to be the greatest of Greek philosophers) back to Epicurus and to the originators of the atomic theory, Democritus and Leucippus. Dalton's theory of atoms is historically the Greek theory of atoms. But with a difference.

Boyle, who was a far more thoroughgoing atomist than is generally supposed, really rejects the hypothesis of different elements which he himself originated, considering that differences of atomic structure and arrangement of a single form of matter would account for all chemical transformations.[2]

But Boyle's own definition of an element, as a substance which could not be decomposed, proved far more fruitful than his atomic beliefs, and the work of his successors—of Marggraf, of Black and Cavendish, of Scheele and Bergman, of Priestley and Lavoisier—had gradually established in the minds of chemists the idea, rejected by Boyle, that there existed a series of elements not convertible into one another. It was to that series of elements, unknown to the ancients, that Dalton applied the atomic hypothesis. He came to the conclusion that the atoms were not of all kinds of shapes and forms, as had been previously supposed, but that the atoms of the same element were all identical in weight, while the atoms of different elements were different in weight. It was an idea that might conceivably have occurred to some chemist fifty years earlier. But, in spite of Black's work, the phlogiston theory had led chemists before Lavoisier to lay small stress on the notion of weight. Dalton could hardly have come much earlier than he did. The first announcement of his theory was made in a paper read in October, 1803, at a meeting of the Manchester Literary and Philosophical Society, in the house of which he had his laboratory; the paper was not published until 1805. Dalton's views were not fully placed before the world until the publication of the first volume of his "New Systems of Chemical Philosophy," in the years 1808–1810.[3]

Meanwhile Dalton had been carrying out researches which confirmed his view, and, together with certain assumptions, led to the most important of generalisations. Dalton himself never disengaged the

1 Save for an obvious clerical error of 1805 for 1803.

2 "I see not, why we must needs believe, that there are any primogeneal and simple bodies, of which, as of pre-existent elements, nature is obliged to compound all others. Nor do I see why we may not conceive, that she may produce the bodies accounted mixt out of one another by variously altering and contriving their minute parts, without resolving the matter into any such simple or homogeneous substances, as are pretended" ("The Sceptical Chymist," part vi., folio edition, vol. i., p. 369). See also p. 366, a reference to an experiment by which Boyle thought he had "destroyed refined gold and brought it into a metalline body of another colour and nature"; and p. 367, an earlier announcement of the view just quoted.

3 The first part of this volume appeared in 1808, the second in 1810. The first part of the second volume only appeared in 1827. The work was not completed.

facts from the theoretical language in which he clothed them. But we may say, broadly speaking, that Dalton's atomic theory led to the establishment of three fundamental laws of chemistry, the law of definite proportions,[1] the law of multiple proportions (which really includes the law of definite proportion) and the law of equivalents. The fact that elements unite in more than one ratio by weight obviously made further assumptions necessary, over and above the atomic hypothesis, before any table could be drawn up of relative atomic weights. Dalton seemed to have felt no hesitation in making the assumptions that seemed to him convenient ("New System," part i. p. 214). But Wollaston, while giving Dalton's theory his powerful support, showed, in 1814, that Dalton's assumptions were arbitrary, and Wollaston's term "equivalent," which was regarded as implying no hypothesis, soon became a serious rival to the term "atomic weight." Davy, to whom (with Henry) Dalton had dedicated part ii. of the "New System" in 1810, gave Dalton's views a reception more than cool.[2]

Among the great chemists of the day, it was to Berzelius, who had already been trying to extend the quantitative work of Richter, that Dalton's views appealed most. But Berzelius, less imaginative, but more critical a thinker and more accurate a worker, than Dalton, saw that much remained to be done before the theory could be placed on a satisfactory basis. "I think," he writes to Dalton, "that we must let experiment mature the theory." Berzelius's admirable "Essai sur les Proportions chimiques" of 1819[3] gives the first critical account of the atomic theory, while the experiments recorded therein may be regarded as having first placed the laws of multiple proportions and of equivalents on a sufficiently wide basis to be regarded as generally valid.

Nevertheless, the conviction that chemistry could do quite well without the conception of atoms, and that the notion of "equivalents" was sufficient, grew steadily; between 1840 and 1850 Leopold Gmelin's system of equivalents came to be accepted almost universally.[4] It was the growth of organic chemistry and the confusions in organic chemistry which the "equivalent" conception was powerless to remove that restored the notion of the atom. From 1842 onwards Laurent and Gerhardt, those two Ishmaels of their day, fought indefatigably for the establishment of some consistent theory of organic compounds; and they reached consistency only by reviving the simple molecular hypothesis of Avogadro and Ampère.[5] This hypothesis gave them at once an experimental method for the determination of the relative molecular weights of all volatile compounds; and it gave them simultaneously a method for determining maximum values for the atomic weights of the elements therein contained, for obviously each molecule must contain at least one atom. But neither they, nor Cannizzaro later, were able to give any simple rule applicable in all cases to the determination of atomic weights. The atomic weight of carbon on which the reform of Laurent and Gerhardt pivoted was an exception to the rule of Dulong and Petit on which Cannizzaro, with general approval, has laid so much stress. But a hypothesis may be useful without being perfect. The atomic hypothesis in the hands of Wurtz, Hofmann, Williamson, Frankland, Kekulé, and Baeyer, and with the most brilliant and essential but involuntary help of Berthelot and of Kolbe, was the instrument which served to build up modern organic chemistry. It gave chemists an unforeseen mastery over the elements; the synthesis not only of the natural organic compounds, but of an infinity of new ones seemed to be brought within their reach. In this development Manchester had again played a part of first-rate importance. Frankland's theory of valency was based on his researches on the organometallic bodies carried out in the Owens College, where he was professor, and published in 1852. The exact *rôle* of Frankland's work on valency (neglected at first by most chemists) was this: it forced his friend and fellow worker, Kolbe, to abandon the Berzelius copula theory, and led him to build up "constitutional" formulæ for the chief alkyl compounds so near our own that he was enabled to predict from them the existence of secondary and tertiary alcohols. The formulæ of Kolbe, with the atomic weights of Gerhardt, again led inevitably to the great theories of Kekulé on the tetravalency of carbon and the linking of the atoms, which are now regarded as fundamental in organic chemistry.

In 1875, new horizons were brought into view. Wollaston predicted of Dalton's atoms in 1808 that "the arithmetical relation alone will not be sufficient to explain their mutual action, and that we shall be obliged to acquire a geometrical conception of their relative arrangement in all the three dimensions of solid extension." Le Bel and van 't Hoff, by their work on the "asymmetric" carbon atom, created a new "chemistry in space," of which one of the most striking results has been the beautiful synthesis of the sugars, by Emil Fischer and his fellow workers. Prof. Pope has recently extended these new ideas to inorganic chemistry with brilliant results.

But such exceptional results as those of Prof. Pope bring sharply into view the fact that the direct service of the atomic theory to inorganic chemistry has been relatively small. What, for instance, has the theory of valency to tell us about such a series of compounds as the tungsten chlorides discovered by Roscoe? But if the atomic theory has helped us comparatively little in determining the constitution of inorganic compounds,[1] it has contributed to our discovery of new inorganic elements. The attribution of certain numbers, equivalents or atomic weights, to the elements led naturally to speculation on mathematical relationships between them. Many of these speculations, like the original one of Prout in 1815, and that of Dr. Henry Wilde, of Manchester, more recently, were suggested by the fascinating question of the fundamental unity of all matter. Are the elements really compounds of one original matter—the *protyle* of the Greeks revived by Prout and by Sir W. Crookes? If so the atomic weights must have some common measure. On the accurate determination of atomic weights, made largely to settle this question, infinite pains have been spent by Stas, Marignac, Richards, and many others. On the criticism and accurate calculation of results from these experimental determinations infinite pains have again been spent, by Meyer and Seubert, and above all by Prof. F. W. Clarke, who delivered the Wilde lecture of the Manchester Literary and Philosophical Society at the centenary celebrations last week.

But though certain numerical relations seem striking, chemists are certainly as a body not inclined to acknowledge the existence of any exact formula expressing as a mathematical series the series of the atomic weights.

More immediately fruitful of results have been speculations less fundamentally ambitious. The schemes of Lothar Meyer and Mendeleeff, according

[1] The present writer has briefly discussed the history of this law, in NATURE, vol. l. 1894, p. 149.
[2] In two unappreciative lines in a footnote to the "Elements of Chemical Philosophy," published in 1812 (see p. 78 of the edition of 1860).
[3] The Swedish edition appeared earlier.
[4] Gmelin himself in his "Handbook of Chemistry" inclined to the atomic theory. English edition, translated by H. Watts, vol. i. p. 42.
[5] "Equal volumes of all gases under the same conditions of temperature and pressure contain equal numbers of molecules."

[1] The researches of Divers and of Raschig on certain sulphur and nitrogen compounds may be regarded as examples of what may be done in this direction.

to which the elements, when arranged in the order of their atomic weights, take their place on a kind of chessboard, elements resembling one another being in the same row, have led to the prediction of the existence of new elements; and even unpredicted new elements, such as the remarkable series discovered by Lord Rayleigh and by Sir William Ramsay, have had a fairly comfortable place found for them by extending the chessboard on ground to which it had some legitimate claims.

Inorganic chemistry has developed recently very largely on the physical side. In much of the work, notably in the applications of thermodynamics (and especially of the researches of Willard Gibbs, whose death we lament), the atomic theory plays no part, or but a small one. In the great studies on solutions, however, originated by van 't Hoff, Arrhenius, and Ostwald, the fruitful *ion* theory formulated by these chemists can hardly be regarded as independent of the atomic theory. And yet, in his last book on inorganic chemistry, Prof. Ostwald employs "the forms of the atomic hypothesis as sparingly as ever the present use of language will permit."[1]

In what has preceded, the atomic theory has been regarded from the point of view of utility. Of its utility to chemistry there can be no doubt. It helps us to describe complicated phenomena briefly. The atomic formula $CH_3.COOH$ reminds organic chemists at a glance of a very large number of properties of acetic acid. But, many will ask, is this atomic theory something more than useful? Is it really true?

The subject has been much discussed of late both by men of science and philosophers.[2] One school regards the methods of experimental science as capable of yielding generalisations that are absolutely true, and some of the members of this school do not hesitate to say that the atomic theory is absolutely true. Sir Arthur Rücker concluded his brilliant address to the British Association in 1901 by declaring that "we have a right to insist—at all events till an equally intelligible rival hypothesis is produced—that the main structure of our (*i.e.* the atomic) theory is true; that atoms are not merely helps to puzzled mathematicians, but physical realities." Even in this most positive assertion of Sir Arthur Rücker with regard to the existence of atoms there remains a shade of doubt. Lord Kelvin, in a subsequent speech, showed that in his mind, at any rate, there was none.

There is, however, another school, the origins of which go back far, but which is identified chiefly with Kirchhoff (the discoverer with Bunsen of spectrum analysis), and with his disciples Mach and Ostwald in Germany, and Karl Pearson in England. According to this school, the discovery of "causes" and of ultimate truths is not the business of experimental science. The object of science, according to Kirchhoff, is to describe natural phenomena in the simplest way possible. If a theory like the atomic theory helps us to describe observed phenomena more simply and to discover new ones, let us use it by all means. But (they would say) since the existence of atoms cannot be verified directly,[3] it is really useless for scientific purposes to discuss whether the theory is true or not. Obviously, science here abandons those claims to finality which have been insisted on so strongly by the older and more orthodox school, for our simple descriptions are liable at any moment to be replaced by descriptions still more comprehensive and still more simple. It would be hard indeed to prove that any given theory has attained a maximum of simplicity in summarising the facts with which it deals.

1 "Principles of Inorganic Chemistry." Translated by A. Findlay, 1902, p. 146. (Macmillan and Co., Ltd.)

2 See Prof. James Ward's "Naturalism and Agnosticism," 2 vols., 1899.

3 "No physicist or chemist can produce a single atom separated from all its fellows and show that it possesses the elementary properties he assigns to it" (Sir A. Rücker, *loc. cit.*).

Kirchhoff's self-denying ordinance on the part of science leaves, no doubt, a wider field open to the metaphysicians. But *qui trop embrasse mal étreint;* and the limitations of scientific claims which he advocates may well strengthen science in her own proper borders.

The atomic theory has had a long and venerable history; the "solid, impenetrable" particles of Newton were originated by the Ionian philosophers in the fifth century B.C. A hundred years ago the genius of Dalton gave the theory a fresh and still unfinished career of usefulness, and whether we consider it in the light of a truth that cannot ever disappear from science, or rather as an engine serving to fashion and unite our ideas, possibly to be replaced later by an intellectual mechanism still more efficient, our debt to Dalton remains one of the greatest that the world owes to its great men.

P. J. HARTOG.

NOTES.

A SPECIAL meeting of the Physical Society will be held on Friday, June 5, at 5 p.m., at University College, when Prof. Rutherford, of Montreal, will read a paper on radioactive processes. A discussion will follow, in which it is hoped several prominent physicists will participate.

IN reply to a question asked in the House of Commons on Tuesday, Mr. Balfour stated that the Government would contribute to the funds required to send the relief ship *Morning* to the Antarctic at the end of this year, to ensure the safety of the officers and men of the *Discovery*, now ice-bound in Antarctic seas.

THE ninth quinquennial conference of the States adhering to the International Telegraph Convention was opened on Tuesday by the Postmaster-General, Mr. Austen Chamberlain, M.P. The business of the conference will go on from day to day until the end of June. Mr. J. C. Lamb, C.B., C.M.G., the principal delegate of Great Britain, was chosen president of the conference, and Mr. John Ardron and Mr. P. Benton vice-presidents.

M. HENRI BECQUEREL, Paris, and Prof. A. Righi, Bologna, were elected honorary fellows of the Physical Society of London at the last general meeting.

THE *Daily Mail* announces that Mr. Andrew Carnegie has offered to subscribe 10,000*l.* towards the erection of an experimental tank for testing ship models, as a memorial to James Watt.

MR. ANDREW CARNEGIE has offered to give 200,000*l.* for a building for the American engineering societies. It is, says *Science*, to be situated in New York City, and will provide an auditorium, a library and headquarters for five engineering societies.

THE death is announced of Prof. C. A. Bjerknes, professor of pure mathematics at the University of Christiania, at the age of seventy-eight, and of Dr. G. C. Dibbits, formerly professor of chemistry at Utrecht, at the age of sixty-four.

THE death is announced of M. Félix Worms de Romilly, a former president of the French Physical Society, who served for many years on the council, and who in addition contributed liberally towards the cost of certain publications undertaken by the Society.

THE *Bulletin de la Classe des Sciences* (Brussels) announces the death, at the age of seventy-six, of M. Charles de la Vallée Poussin, professor of mineralogy and geology of the University of Louvain, and author of important geological papers published in the *Bulletin* itself

and in the *Annales* of the geological and scientific societies of Brussels.

A REUTER message from Stockholm, dated May 22, states that the expedition which is being fitted out to relieve the Nordenskjöld Antarctic Expedition will be provided with stores for three years. It will be under the command of Captain Gylden, of the Swedish navy, who was in charge of the expedition sent to Spitsbergen in 1901 for the measurement of an arc of meridian.

A CORRESPONDENT of the *Times* states that an earthquake was widely felt in Turkish Armenia on April 29. More or less severe shocks were experienced from Van to Baiburt, on the north-west, and it is feared that the loss of life has been extensive. So far no actual details as to the effects of the earthquake seem to have been received, except some relating to the military losses at a town about 100 miles north of Erzerum.

THE annual report to the Conseil de l'Observatoire de Paris, which M. Maurice Loewy is preparing for publication, will contain an account of the recent observations made at Greenwich and Paris for the determination of the difference of longitude between the two observatories. In each observatory a French and an English astronomer made observations independently in the spring and autumn of last year, and a Paris correspondent informs us that the discussion of the two series shows no sensible difference between the French and English results. When the calculations have been completed, the results will be described in papers to be presented at the same time to the Royal Society and the Paris Academy of Sciences by Mr. Christie and M. Maurice Loewy respectively.

THE Australasian Association for the Advancement of Science will hold its next meeting at Dunedin in January, 1904, under the presidency of Prof. T. W. E. David, of Sydney University. The sections and their presidents will be as follows:—A—astronomy, mathematics, physics, and mechanics, Prof. W. H. Bragg; B—chemistry, Mr. J. Brownlie Henderson; C—geology and mineralogy, Mr. W. H. Twelvetrees; D—biology, Colonel W. V. Legge; E—geography, Prof. J. W. Gregory, F.R.S.; F—anthropology and philology, Mr. A. W. Howitt; G—(1) social and statistical science, president not yet appointed; G—(2) agriculture, Mr. J. D. Towar; H—architecture, engineering, and mining, Mr. H. Deane; I—sanitary science and hygiene, Dr. Frank Tidswell; J—mental science and education, Mr. John Shirley.

THE annual congress of the South-eastern Union of Scientific Societies will be held at Dover, June 11–13. On Thursday evening, June 11, the president-elect, Sir Henry H. Howorth, F.R.S., will deliver the annual address. The following papers will be read on June 12:—Atmospheric moisture as a factor in distribution, by Mr. A. O. Walker; experiences of leprosy in India, by Dr. Jonathan Hutchinson, F.R.S.; the diminution and disappearance of south-eastern flora and fauna within the memory of present observers, by Captain McDakin and Mr. Sydney Webb; the seedlings of geophilous plants, by Miss Ethel Sargant; the white chalk of Dover, by Dr. Arthur Rowe; a late Keltic cemetery at Harlyn Bay, by Rev. R. Ashington Bullen. On June 13 Mr. A. T. Walmisley will lecture on international communication.

THE first section of the London County Council's electrical tramways, opened a few days ago by the Prince and Princess of Wales, is of special interest because in the electrification of this tramway the conduit system has been adopted instead of the overhead trolley system, which has been almost universally installed elsewhere throughout the country. The appearance of the line is unquestionably very much superior to that of lines equipped on the overhead system, but it remains to be seen whether it will work equally well in practice; for this reason the working of the new lines will be watched with special interest during the next few years. The cost of installing the conduit system has proved much greater than that of equipping an overhead system, and it is to be hoped that some other advantages will be found to result in working in addition to the gain in appearance, as the district can hardly be said to be one of such great natural beauty that overhead lines would have spoilt it.

THE Middlesex Hospital at the beginning of this year established a complete electrical installation for electro-medical work. The equipment includes all the necessary apparatus for X-ray work, high-frequency, Faradic and galvanic treatment. There are two Finsen lamps for the treatment of lupus, and experiments are also being tried in the treatment of this disease by the Cooper Hewitt mercury vapour lamp. The greater part of the apparatus has been set up in a special temporary building. This is already being found somewhat too small for the number of patients passing through, which amounts to about three hundred a week. Two trollies fitted with apparatus and coils for treatment and radiographic work have also been equipped. It is stated that the results obtained in cases of lupus have been most satisfactory, and that the X-ray treatment of cancer is also giving promising results. The high-frequency treatment of cancer has not been found as yet to justify the claims made in its favour, but further experience and observation are required.

A *Daily Mail* correspondent at Rome states that shortly before eleven a.m. on May 22, an earthquake shock was felt throughout Italy.

ROBINS frequently build in curious places. Miss E. M. Milner sends from Stafford a photograph of a robin's nest built in a small leather handbag that was hung in an arbor near her house. Five eggs were laid and hatched in this nest.

REFERRING to the discovery of a radio-active gas in water by Prof. J. J. Thomson (April 30, p. 609), and the demonstration by Prof. Rutherford that the emanation from radium and thorium is a gaseous body, Mr. W. A. D. Rudge writes to suggest that some interesting results might be obtained from the examination of the gases withdrawn from deep mines for the purpose of ventilation. Mr. Rudge also suggests that these radio-active gases may be of the nature of metallic carbonyls, "because they are the only known metallic compounds which are gaseous to any extent at ordinary temperatures."

THE Meteorological Council has issued a notice stating that it will, as before, supply forecasts of weather during the summer months (June to September inclusive) for the benefit of agriculturists and others as was arranged last year. These forecasts are sent by telegraph at about 3h. 30m. p.m. to those who express a wish to receive them regularly, and who defray the cost of the telegrams, which will be so worded that the cost of each message will be 6*d*. for any one district, including an address of three words. This service of harvest forecasts is, in addition to the ordinary service of forecasts, prepared at 11h. a.m. and 8h. p.m. The harvest forecasts refer to the weather of the next day.

INTERNATIONAL scientific balloon ascents were made on the morning of March 5; the balloons were both manned and others equipped with recording instruments only, while

at some stations kites were used. We quote only the preliminary results of the registering balloons, as these attained the greatest altitudes. At Trappes, near Paris, a temperature of $-49^{\circ}.8$ C. was registered at 10,000 metres; the reading at starting was $9^{\circ}.6$, and an inversion of $0^{\circ}.2$ occurred at 750 metres. The balloon rose to 15,700 metres, but if readings at higher altitudes than those quoted are suspected of being vitiated by radiation, they are scrupulously rejected. At Strassburg, the temperature at starting was $6^{\circ}.3$, and the following readings were recorded:—$-59^{\circ}.1$ at 15,600 metres, $-54^{\circ}.0$ at 10,300 metres, $-51^{\circ}.5$ at 12,200 metres. A second balloon, on March 6, recorded $-62^{\circ}.1$ at 15,330 metres, $-51^{\circ}.2$ at 10,200 metres, and $-48^{\circ}.2$ at 11,300 metres. At Berlin the following temperatures were recorded:—$-57^{\circ}.0$ at 10,400 metres, $-51^{\circ}.0$ at 12,000 metres; at starting $4^{\circ}.4$. The type of weather was cyclonic over the British Isles and west of Scandinavia, and anticyclonic over south-west France and eastern Russia.

There has recently been some discussion in the columns of our contemporary *Science* as to who first made use of the word "barometer." It occurred in a paper by Boyle in the *Phil. Trans.* of 1666, and also in an anonymous article in the same journal in 1665. Our valued correspondent, Mr. A. L. Rotch, refers to the use of the word in 1665 in "The General History of the Air . . . by the Honble. Robert Boyle, Esq.," published in London in 1692. We have referred to the work and to the article in question, viz. "A Short Account of the Statical Baroscope, imparted by Mr. Boyl, March 24, 1665. In a Letter to Mr. H. Oldenburgh." As the matter may be of interest to our readers, we quote the sentence (p. 98):—"When I come to another Place, where there is a Mercurial Barometer, as well freed from Air as mine (for that must be supposed) if taking out my Scale-Instrument, it appears to weigh precisely a Drachm; and the Mercury, in the Baroscope there, stand at 29¾ Inches, we may conclude, the Gravity of the Atmosphere, not to be sensibly unequal in both those two Places, though very distant."

During the summer months of the years 1900–1902, the cutter yacht *Walwin*, belonging to Dr. R. N. Wolfenden, was engaged, under the owner's direction, in taking sea temperature observations at the surface and at various depths, and in the collection of samples of water in the channel between the Shetland and Faeroe Islands. The discussion of the observations was entrusted to Mr. H. N. Dickson, who has communicated the results in an interesting paper to the *Geographical Journal* for April. There are two opposing movements of water in the channel, from the south and from the north. The former, or north-moving currents, are of two kinds:—(*a*) drift currents caused by the winds; these are strongest during winter; and (*b*) stream currents, or the Norwegian branch of the European stream; these are strongest during summer. The south-moving currents are also of two kinds:—(*c*) water from the central and western parts of the Norwegian sea, and (*d*) water derived from the melting of ice in the Arctic regions. One of the conclusions drawn by the author is that the movements of the surface waters of the sea and the temperature of the air near the British Isles do not stand in any direct relation of cause and effect. The temperature of the surface water influences the distribution of atmospheric pressure, and will therefore affect the direction of the prevailing winds, but motion has nothing to do with this influence.

An exhibition of mounted heads of the larger mammals and other products of the chase from the German Colonies (Deutsch-Kolonial Jagd-Austellung) has lately been opened at Carlsruhe, under the patronage of the Grand Duke Frederick of Baden. More than fifty persons, who have been out in the German Colonies as officials or in quest of sport, have sent their trophies to it, and a most extensive and instructive series of specimens is the result, which no one interested in the larger game-animals should fail to see. The well-known traveller and naturalist, Oscar Neumann, has contributed the whole of his large African collection. Herr Carl Hagenbeck, of Hamburg, who has long been engaged in getting together a series of heads and horns from all parts of the world, has likewise sent the whole of them to Carlsruhe for exhibition. Amongst the latter the specimens of wild sheep, ibexes and deer from Central Asia have attracted much attention. The collection will be open to view all the summer in the building of the Jubileum Art Exhibition, at Carlsruhe.

Captain Stanley Flower, the director of the Zoological Gardens at Gizeh, near Cairo, is expected to arrive in England about the end of this month, and will bring with him a valuable contribution to the Zoological Society's menagerie. This is a male Grévy's zebra, by far the largest and finest member of the group of African striped asses. There are already two female examples of this beautiful animal in the Zoological Society's Gardens, which have been placed under the Society's care by H.M. the King, so that the acquisition of a male of the same species is eminently desirable. The male in question was obtained for the Society by Colonel Harrington, the British Resident at the capital of Abyssinia, and was brought down as far as Cairo in December last. But it was thought prudent to keep the animal in a warmer climate during the winter season, so it was arranged to deposit it at Gizeh under Captain Flower's care. It is hoped that Captain Flower will likewise be able to bring to England on the same occasion another female of the same species of zebra, also obtained for the Zoological Society by Colonel Harrington.

An important series of statistical articles dealing with the occurrence and incidence of cancer in various countries has been published in the *British Medical Journal*. The main conclusions arrived at are that cancer is prone to attack certain races, especially the Scandinavian and the different branches of the Germanic family, that it is more prevalent in districts in which beer is the staple drink, and that it tends to cause excessive mortality in regions abounding in water, and to a much more marked extent when these are covered with woods or forests.

The well-known salmon disease, since the researches of the late Prof. Huxley, has always been regarded as being caused by the attack of a fungus, the *Saprolegnia ferax*. Recently Mr. Hume Patterson has conducted a research for the Fishery Board for Scotland, and has come to the conclusion that the disease is due to vasion of the tissues of the fish by a special bacillus (*B. salmonis pestis*), which gains access through some abrasion or ulceration of the skin. When the skin of the fish is in a healthy state, the disease is apparently not contracted. The bacillus remains alive in the dead fish, which therefore prove a source of infection, and should immediately be removed and burnt as soon as they are observed.

Various explanations have been given of the cause of the phenomenon of agglutination, the aggregation of the bacteria into clumps, that occurs when an immune serum is added to a bacterial culture. A substance termed agglutinin develops in the serum as the result of immunisation (also frequently during an attack of infective disease, *e.g.* typhoid fever), which combines with some constituent in

the bacterial cell. Dr. A. E. Wright suggests that this combination alters the electrical relations of the fluid and suspended particles (bacteria) so that these then offer an appreciable resistance. The electric currents generated by the ionisation of the salts in solution would tend to drive these interposed resisting particles out of the direct line of action, and the displaced particles would all tend to find a position of rest in the angles between the intersecting lines of force, and so clumping would result. (*Lancet*, May 9, p. 1299.)

MUCH work has of late years been carried out upon the nature and physiological action of the venoms of poisonous snakes. The latest contribution to the subject is a memoir by Captain Lamb and Mr. Hanna upon the venom of Russell's viper (*Daboia Russellii*). They find that Daboia venom owes its toxic property chiefly to its action upon the blood, the rapid death which results being mainly due to extensive clotting of the blood in the blood-vessels. Heating a weak solution of the venom (0·1 per cent.) for half an hour to 73° C. completely destroys the toxicity, though a more concentrated solution (1 per cent.) may have its toxicity only lessened by this treatment. Daboia venom and cobra venom differ in two respects; cobra venom contains a toxic substance of the nature of an albumose, which acts especially upon the central nervous system, and is the essential poisonous constituent, whereas it contains no substance causing intra-vascular clotting. Daboia venom, on the other hand, contains no toxic element having an action similar to that of the toxic albumose of cobra venom. Calmette's anti-venin, which has a powerful neutralising action for cobra venom, possesses little or no such property for Daboia venom. (*Scientific Memoirs of the Government of India*, No. 3, Calcutta.)

PART i. vol. iv. of the *West Indian Bulletin* contains a complete record of the observations of atmospheric phenomena at various points on the island of Barbados during the fall of volcanic ash following the eruption of the St. Vincent Soufrière on March 22 last, together with the results of the chemical analysis of the ash by Prof. d'Albuquerque, and of the mineralogical analysis by Dr. Longfield Smith. The latter states that the minerals present were the same as those found in previous falls, but the relative proportions differed very considerably, the most striking feature, which at once distinguish the late fall from former ones, being the large amount of magnetite and hæmatite present. There was only a small proportion of glass, which was of two kinds—a clear, colourless to brown variety, enclosing microlites and often crystals of felspar, and a translucent to opaque variety, the latter often brown, owing to numerous hæmatite inclusions.

THE Imperial Department of Agriculture for the West Indies is giving some attention to the question of improving the corn yield of the islands for estate purposes. At present enormous quantities of corn have to be imported, for the islanders grow corn only as a catch crop, which is often planted at wide distances apart, and little or no attention is given to it. As a result the yield of corn averages only about ten bushels per acre, the quality grown containing 10 or 11 per cent. of protein. In a recent number of the *Agricultural News* it is stated that much better results "may be attained without the aid of elaborate chemical analyses, and with no more apparatus than a pen-knife, an observant eye, and the expenditure of a certain amount of care and time." Based upon the investigations of Prof. Hopkins, of the University of Illinois, simple instructions are given for making a chemical selection of ears of seed-corn by a simple mechanical examination of the kernels, thus enabling farmers to separate the high-protein from the low-protein seeds. It is hoped by adopting this method of corn-breeding to increase the protein yield by about 2 per cent., while the greater care devoted to the cultivation would necessarily lead to a substantial increase in the quantity of corn produced per acre.

AN interesting account of the works of the late Sir G. G. Stokes is given by Prof. W. Voigt in the *Nachrichten* of the Göttingen Academy, 1903, part i.

THE Actien Gesellschaft für Anilin Fabrikation, of Berlin, send their price list of dry plates, developers, and other requisites for photography, which they manufacture under the registered name of Agfa.

CONSIDERABLE uncertainty has prevailed as to the existence of conjugation in the Amœbæ. In the *Atti dei Lincei*, xii. 7, Signora Margherita Traube Mengarini publishes a paper on the subject. The authoress has been sufficiently fortunate to observe a process of true conjugation in *Amoeba undulans*, apart from the process of fusion observed by Zaubitzer and Maggi. This process lasts but a short time, and it ends in the complete separation of the animals, so it is difficult to study the phenomenon in its entirety.

IN connection with the debated question of the magnetic action of convection currents, MM. Crémieu and Pender have undertaken a series of experiments the results of which are summed up in the *Bulletin* of the French Physical Society. They now definitely prove that metallic surfaces turning in air, either with or without the presence of parallel armatures, produce magnetic effects agreeing to within 10 per cent. of the amounts required by the convection theory. A further mode of experimenting is described by M. Vasilesco Karpen, who produces an alternating convection current by rotating an ebonite disc charged by an alternating current.

M. LÉON GUILLET contributes some interesting notes to the *Bulletin* of the French Physical Society on the metallography of nickel steel. The steel was of three different classes, the first having the same structure as carbon steel, the second (mertensite) having the structure of tempered steel, and the third a polyhedral structure. It is found that these classes differ notably in their behaviour when subjected to tempering, heating, extreme cold, and decarburation, and M. Guillet finds a close relation between the mechanical properties of the steel and its micrographic structure.

UNDER the title of *Zeitschrift für wissenschaftliche Photographie, Photophysik und Photochemie*, a new journal has been brought out by Messrs. Ambrosius Barth, of Leipzig. The editors are Dr. E. Englisch (Stuttgart) and Prof. K. Schaum (Marburg), with whom Prof. H. Kayser (Bonn) has cooperated. The first number contains papers on Kirchhoff's laws, by F. Richarz and A. Pflüger; on the photochemistry of silver iodide, by Lüppo-Cramer; and on stereoscopic photography of microscopic objects, by W. Scheffer, the last paper being illustrated by a plate showing stereoscopic representations of a fly and other objects. A noteworthy feature is the collection of abstracts of papers dealing with physical and physiological optics, radiography, photography, and allied subjects, which are to include electricity and wireless telegraphy.

THOSE who are engaged in the teaching of elementary experimental physics will find a mine of wealth in Prof. Bohn's newly-published illustrated catalogue of instruments

and models taken from the Schäffer Museum. The late Hermann Schäffer, whose death was announced in 1900, and who held a chair of mathematics and physics at the University of Jena from 1856 onwards, devoted a large portion of his lifetime to the formation of this collection, which consists of models and instruments constructed for the express purpose of illustrating in the clearest and simplest way the elementary properties of matter, light, heat and electricity. Prof. Bohn describes about 350 apparatus out of a collection of many thousands now housed in the Zeiss Institution in Jena. A noteworthy feature of Schäffer's methods was the great use he made of glass in order that his pupils might see the complete working of the experiments.

WE have received a copy of the second number of a new paper called the *British Inventor*. The new journal contains a few brief notes on scientific novelties, but is chiefly concerned with popular and trade aspects of invention.

WE have received a copy of a catalogue of the Romanised geographical names of Korea, compiled by Prof. B. Kotô and Mr. S. Kanazawa, of the Imperial University of Tōkyō, Japan. The catalogue is published by the Tōkyō University, and should prove of great assistance to travellers in the interior of Korea.

FIVE more parts of the first annual issue of the "International Catalogue of Scientific Literature" have just been published. These newly issued volumes include the second part of vol. iv., which deals with works on physics; vol. x., mathematical and physical geography; vol. xi., mineralogy, including petrology and crystallography; vol. xii., geology; and a volume giving a list of journals with the abbreviations used in the catalogue as references.

THERE has been issued from the Government Printing Office, Washington, U.S.A., a reprint of a "Bibliography of Cooperative Cataloguing and the Printing of Catalogue Cards (1850–1902)," by Messrs. Torstein Jahr and Adam J. Strohm, which was included in the report for 1902 of the Librarian of Congress. In view of the cooperative plans of the Royal Society, the Brussels Institut international de bibliographie, and the Concilium bibliographicum at Zurich for the production of international catalogues of scientific works, the publication of this list of works should interest many European men of science.

PARTS I. AND II. of the *Transactions* of the Royal Society of Edinburgh, dealing with the work of the sessions 1900–1902, have now been published by Messrs. R. Grant and Son, of Edinburgh, and Messrs. Williams and Norgate, of London. Among the twenty contributions to the two volumes, the following may be mentioned as of wide scientific interest: Dr. Masterman's contribution to the life-histories of the cod and whiting; the second part of Sir William Turner's study of the craniology of the people of the Empire of India; Mr. Aitken's notes on the dynamics of cyclones and anticyclones; Mr. Harker's paper on ice-erosion in the Cuillin Hills, Skye; and Dr. Scott's investigation of the primary structure of certain palæozoic stems with the Dadoxylon type of wood. The reports published from time to time in our columns of the meetings of the Royal Society of Edinburgh make any detailed reference to the contents of these volumes unnecessary.

SECOND editions have been issued of Mr. M. M. Pattison Muir's translation of Dr. Robert Lüpke's "Elements of Electro-chemistry Treated Experimentally" (Messrs. H. Grevel and Co.), and of Mr. George Massee's "Text-book of Plant Diseases caused by Cryptogamic Parasites" (Messrs. Duckworth and Co.). Mr. Pattison Muir has incorporated the important changes and additions made by the author in the third German edition, and also added about a dozen new illustrations. Mr. Massee has taken the opportunity to deal in the new edition of his book with several destructive diseases which either have appeared for the first time or have developed and extended to an alarming extent since the appearance of the first issue of his work.

THE fifth edition of the "Introduction to the Study of Metallurgy," by the late Sir William Roberts-Austen, published by Messrs. C. Griffin and Co., Ltd., was fortunately completed by its distinguished author before his death, and has now made its appearance. The book has again been enlarged and improved, and in its present form is necessary to every student of metallurgy who desires to obtain a general view of his subject. Besides being one of the most readable of scientific works, it will provide Sir William Roberts-Austen's many friends with an interesting memento. The two presidential addresses delivered by the author before the members of the Iron and Steel Institute in 1899 and 1900 are printed in an appendix, and the whole volume is a token of the interest he took in the welfare of his students.

THE latest issue of the memoirs of the Société de Physique et d'Histoire Naturelle de Genève contains the president's report for the year 1902, together with a monograph by the late M. Marc Micheli on the Leguminosæ collected in the Mexican States of Michoacan and of Guerrero during 1898 and 1899 by the late M. Eugène Langlassé. The voyage of M. Langlassé had utilitarian ends in view, and his attention was especially directed to plants of interest to the horticulturist, and likely to prove important from the point of view of agriculture, rather than for their scientific interest. Notwithstanding this fact, the number of new species contained in his collection shows conclusively that many new forms will be forthcoming when the country visited by M. Langlassé is systematically explored by competent botanists. Among the 237 kinds of leguminous plants collected, M. Micheli described twenty-six as new species, and he admits one new genus. The monograph is accompanied by twenty-eight beautifully executed plates, which serve as an admirable accompaniment to what proved to be the last piece of work of the author.

IN accordance with a resolution passed at the International Geological Congress at Paris in 1900 to establish a palæontological publication to bring together illustrations and descriptions of type-fossils, an international committee was appointed to prepare a programme of the publication which is to be known as "Palæontologia Universalis." The commission will publish each type-fossil on a separate plate. It has been arranged to reproduce the original figure of the type-fossil, to give a phototypographic figure of the type itself, the original description without alterations or abbreviations, and additional observations by the authors. The two specimen plates which have reached us are excellent, and the series, when complete, should be of great service in making known rare and frequently unknown descriptions and figures of type-fossils. The assistance of numerous palæontologists has been secured, and they will prepare the plates of the type-fossils of the greatest interest in the collections in their care. Dr. von Zittel is president of the committee, and M. D. P. Œhlert is the secretary. The British members are Messrs. F. A. Bather and A. Smith Woodward. The annual subscription is 1*l.* 12*s.*, which should be sent to Messrs. William Wesley and Son, 28 Essex Street, W.C.

THE extraction of the perfume from flowers such as jasmine, tuberose, violet and cassia has long been carried out by the process of enfleurage, the blossoms being left in contact with purified lard for a few days, and then replaced by fresh blossoms. The lard is either sold as such, or the essential oil may be extracted from it by melting it under strong alcohol. As the process of enfleurage is somewhat tedious, attempts have frequently been made to extract the oil directly from the flowers by means of light petroleum, but these processes have not as a rule proved successful, and it has recently been found that a very large proportion of the perfume is actually produced for the first time in the blossoms during the time occupied by the enfleurage. An interesting illustration of this is given by Dr. Albert Hesse in a recent number of the *Berichte*, in which he states that a ton (1000 kilos.) of tuberose blossoms only yielded 66 grams of oil when extracted with light petroleum, but during enfleurage yielded 801 grams of oil to the fat in which they were embedded, whilst a further 78 grams remained in the faded blossoms and could be separated by extraction or distillation. It thus appears that eleven times as much perfume is produced during enfleurage as is originally present in the flowers, and that even after enfleurage the exhausted flowers contain more perfume than when first gathered.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Captain Lambert Larking; a Naked-footed Owlet (*Athene noctua*) from Holland, presented by Mr. R. Souper; a Common Cormorant (*Phalacrocorax carbo*), British, presented by Mr. C. F. McNiven; a Nilotic Trionyx (*Trionyx niloticus*) from West Africa, presented by Mr. Henry Reeve; a Common Chameleon (*Chamoeleon vulgaris*) from North Africa, presented by Mr. M. J. Comyn; three Suricates (*Suricata tetradactyla*) from South Africa, ten Black-spotted Lizards (*Algiroides nigro-punctatus*) from Madeira, deposited; a Thar (*Hemitragus jemlaica*), a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

June 3. Predicted perihelion passage of Faye's comet.
,, 15h. Mars in conjunction with moon. Mars 1° 49′ N.
8. 12h. 10m. Minimum of Algol (β Persei).
15. Venus. Illuminated portion of disc=0·613, of Mars =0·885.
,, 11h. Uranus in opposition to the Sun.
17. Juno 1° N. of μ Serpentis (mag. 3·6).
,, 14h. Jupiter in conjunction with the moon. Jupiter 3° 7′ S.
19. 11h. 31m. to 14h. 55m. Transit of Jupiter's Sat. IV. (Callisto).
20. 12h. 52m. Transit (egress) of Jupiter's Sat. III. (Ganymede).
22. 3. Sun Enters Gemini. Summer commences.
27 9h. 28m. to 10h. 5m. Moon occults α Cancri (mag. 4·3).
,, 13h. 36m. to 16h. 46m. Transit of Jupiter's Sat. III. (Ganymede).
,, 16h. Mercury at greatest elongation 22° 5′ W.

VARIABILITY OF NOVA GEMINORUM.—A note from Prof. E. C. Pickering which appears in No. 3868 of the *Astronomische Nachrichten* states that the light of Nova Geminorum appears to be fluctuating in a manner similar to that of Nova Persei, No. 2. During the twenty-four hours preceding the evening of May 1, it had increased by half a magnitude.

The nature and amount of these fluctuations will be seen from the following table of measures made at Harvard:—

Date.	Magnitude.	Date.	Magnitude.
April 24	... 9·37	April 29	... 9·61
,, 25	... 9·67	,, 30	... 9·76
,, 27	... 9·71	May 1	... 9·26
,, 28	... 9·81		

ORIGIN OF THE H AND K LINES OF THE SOLAR SPECTRUM.—In a paper communicated to the April number of the *American Journal of Science*, Prof. J. Trowbridge, of Harvard University, gives the results he has obtained from a series of careful experiments which he made in order to determine the constitution of the H and K lines in the solar spectrum, and also discusses the nature of reversed lines in gaseous spectra.

By a series of preliminary experiments he arrived at the conclusion that the lines which he obtained coincident with the calcium lines were not due to any calcium in the glass tubes or the terminals used in obtaining the spark, and further he argues that, even if the glass did contain calcium, the duration of the spark was not sufficiently long to raise the temperature of the glass high enough for it to produce a spectrum, whilst in obtaining his spectra he photographed a part of the spark which was far enough removed from the terminals to ensure the absence of metallic particles ejected by them.

Using quartz tubes sealed by metallic ends he obtained the reversed line at λ 4227, and also lines coincident with the solar lines 3968 and 3933, quite as strong as when a glass tube was used, whilst the other strong calcium lines towards the ultra-violet were conspicuously absent.

Prof. Trowbridge found that the spectra obtained from a highly disruptive spark discharge between electrodes of some metals do not show these lines, whilst those obtained from a similar spark between other metals, *e.g.* pure silver, platinum and iridium, do show them; he suggests that in the former case the metals are easily volatilised, and their vapours conduct the spark, whereas in the case of the latter class of metals the air conducts the discharge because no metallic vapours are produced, and therefore it is some gaseous constituent of the atmosphere which produces the lines in question. For similar reasons he believes that some lines at present attributed to silicon—another highly refractive substance—are possibly atmospheric.

From these observations Prof. Trowbridge arrives at the following conclusions:—"At the basis of the great H.H lines of the solar spectrum there are strong gaseous lines which I believe to be oxygen lines. The reversed lines which apparently coincide with certain calcium lines are not due to calcium but are gaseous." Reproductions of four spectrograms, which accompany the article, illustrate the reasons for these conclusions.

THE LEEDS ASTRONOMICAL SOCIETY.—The tenth annual issue of the *Journal and Transactions* of this Society contains a series of useful papers which were communicated to the Society by its members during 1902. Amongst others there are papers on "Parallax," "Velocities, Paths and Eclipses in the Solar System" (illustrated by diagrams of the various orbits), "The Age of the Earth," "Brightness and Definition," and "The Year's Observations" (which were in the most part observations of Jovian phenomena), all of which should prove of value and interest to amateur astronomers.

The *Journal* concludes with a collection of the papers and letters communicated to other journals by the members of this Society during 1902.

THE ADVANCEMENT OF PHOTOGRAPHY.

AT the recent meeting of the Royal Photographic Society held to celebrate its jubilee, the president, Sir William Abney, K.C.B., F.R.S., suggested, in an address of which an abridgment is given below, that the Society should further mark the close of the first fifty years of its existence by establishing laboratories and suitable accommodation for the carrying out of photographic researches. A donation of 100*l.* has already been promised, on condition that 900*l.* more is raised for this purpose. The establishment of such facilities is highly desirable, for, excluding the work of a few whose names may be counted on the fingers of one

hand, and that done by our manufacturers, which has, so far, succeeded in keeping them in the van of progress, investigations into the underlying facts of photography may be said to be non-existent in this country. A thousand pounds is a very modest sum to ask for, though no doubt it will serve to make a beginning. We hope that before very long this sum will be multiplied many times over, and that the science of photography will begin to take its proper place, instead of being regarded, as it is too often at present, as a very minor detail of a considerable industry, and an empirical art. The following remarks are from Sir William Abney's address:—

Looking back to the first day of this Society's existence, one is forcibly reminded of the advances that have been made, not only in the science, but in the art of photography, but these advances I think might have been more rapid. A very brief comparison of the processes existing now and fifty years ago will show what I mean. Paper processes, founded on the original process of Fox Talbot, were well to the fore fifty years ago, although in 1851 Scott Archer had shown to the world the practicability of taking photographs on glass by means of collodion. In that same year, when the First International Exhibition was held, calotype, Daguerreotype, and collodion processes were all worked commercially, and photographs of the interior of the Palace by all three processes are in being to-day.

At the present time it may be said that for all practical purposes the gelatine process for taking negatives has complete possession of the field, and ousted all processes which have led up to it. Negatives fifty years ago were impressions only given by the violet and blue rays existing in white light, and the resulting prints are such as would be seen by a person colour blind to the red and the green, whilst now it is not uncommon for the photograph to be made to coincide with visual impression of an ordinary eye.

There seems but little doubt that the photographic image remains of the same nature now as it was then, and whatever may have been the action of light then, so it is now, but the necessary exposure to obtain a properly developable image was at least sixty-fold more than is required for our present process, even when the collodion process was employed, where every condition remained the same except the sensitive surfaces themselves. With the Daguerreotype process perhaps we should have required ten times more than for the collodion, though we know of instantaneous work being done even with that process. For open air portraiture, the early Daguerreotypist required half an hour in bright sunshine, whilst the modern amateur will be content with a second or a fraction of a second in the same circumstances. A question one naturally asks is, What causes the difference? So far as I am aware, this question has not been fully answered, and yet it might have been had serious experiment been undertaken regarding it.

From a theoretical standpoint there are three things that have to be taken into account:—1st, the sensitiveness of the silver salt itself; 2nd, the mediums in which it is placed; and 3rd, the means of development. We have some clue to the last two. Beginning with the last first, those who practised Talbotype or the wet collodion processes know that in both of them the developing solution was an acid solution reduced from nitrate of silver, which was on the surface of the plate or paper, to the metallic state, and that there was some attractive force which caused the metallic silver to adhere to and crystallise on particles of sensitive salt which had been acted upon by light. In the gelatine process we know that development is with alkaline solution, and that the image is built up from the very molecules themselves that have been acted upon, the sensitive salt itself being reduced to metallic silver. Why should development be effected more easily in the one case than in the other? In the case of the acid development the distance of the particles of reduced silver from the molecules altered by light are far greater than they are when the material of the plate is attacked, and consequently a smaller attractive force, due to fewer molecules being altered in the latter case, is efficacious in producing a silver image than in the first case where the depositing silver has a considerable distance into which the attractive force has to be exercised. This might be an explanation. Or, again, it may be shown that a gelatine film, being a kind of filter to the developing solution, acts as a regulator in allowing the active alkaline solution to reach the particles of silver salt, and that this regulated supply would attack the molecules on which light had done part of the work of decomposition, and reached the remaining part most readily to be finished and so on, and that very little external retarding influence was necessary. But now, what is to be said regarding the increased instability of the sensitive salt? This is a question not yet investigated, but it is from such an investigation that increased rapidity is to be looked for.

But it is one thing to say what proof is required, and it is another to have the opportunity of making such proofs, and I should urge that it is part of the duty and functions of the Royal Photographic Society to lead the way in placing such means at the disposal of its members and others as will enable any of them who have the capacity to experiment in this and in any other directions which will lead to a theoretical knowledge of the action of light. It must not be forgotten that there are a great many more men with minds trained to scientific research now than formerly. There are plenty of would-be capable workers who cannot afford a laboratory of their own, and what I should wish to see in this our jubilee year is the commencement of the formation of a research laboratory adapted to the needs of the scientific workers.

One branch of photographic science is the optical, and in it we have an example of what laboratory and experimental research can do when workers are trained in scientific methods. Not many years ago the optician was challenged to increase rapidity of exposure by increased rapidity of lens. Nobly and rapidly he has responded; the advent of Jena glass enabled him to comply with the demand, and we have been getting definition of image with ratio of aperture to focal length which would have been deemed impossible not very many years ago.

I do not believe a laboratory would be an expensive matter to start. What I do advocate is to have all essentials of all instruments of first-class workmanship, and to leave the adaptation of any instrument from one special work to that of another to the worker. Hence, if my views are carried out, the initial expenses will not be so great as might be supposed. Space is the foundation of all research in photography, and that is what the Royal Photographic Society can supply, and then comes the provision of the apparatus necessary to use in such space.

I have heard that one generous man will give 100*l.* to the laboratory if 900*l.* more are raised. The 1000*l.* would go a very long way towards what we want to start with, and I hope the members of the Society will resolve to give substantial help in raising this 900*l.* The jubilee of the Society should be marked by some important piece of work, and no bigger one and more requisite is, to my mind, to be found than starting such a help to the advancement of photography.

RADIO-ACTIVE GAS FROM TAP-WATER.[1]

WHEN Cambridge tap-water is boiled the air given off is mixed with a radio-active gas. The existence of this gas is easily demonstrated by electrical means, for if the air expelled by prolonged boiling from about 10 litres of water is introduced into a closed vessel the volume of which is about 600 c.c., the amount of ionisation in the vessel (as measured by the saturation current) is increased five or six times. When the water has once been well boiled the gas expelled on any subsequent re-boiling is not appreciably radio-active. The gas can also be extracted from water at the temperature of the room by vigorously bubbling air through it; the air as it bubbles through the water gets mixed with the radio-active gas and carries it along with it. When water which has been treated in this way is boiled, no radio-active gas is given out, nor is the gas given off when air is bubbled through water which has been well boiled.

The gas extracted in this way from the water retains its

[1] Paper read before the Cambridge Philosophical Society on May 4 by Prof. Thomson, F.R.S.

radio-active properties after bubbling through strong sulphuric acid, or caustic potash after passing over red-hot copper, or through a narrow platinum tube kept at a white heat; it does not seem appreciably affected when sparks are passed through it.

The gas can diffuse through a porous plate, and by comparing its rate of diffusion with that of CO_2 through the same plate, its density can be determined by Graham's law; preliminary measurements of this kind indicate that two different gases are present, of which one has a density about twice, the other between six and seven times that of CO_2. The gas obtained by boiling the water always diffused faster than that procured by bubbling air through the water; it seems possible that in the latter case the gas may get loaded with water-vapour to a greater extent than in the former.

A negatively electrified surface exposed to the gas becomes radio-active, the induced radio-activity dying away to half its value in about forty-five minutes. Mr. Adams has shown that a positively electrified surface also becomes radio-active when exposed to the gas, though to a smaller extent than if it had been negatively electrified; an unelectrified surface does not become radio-active. In this respect the gas differs from the emanation from radium, which, according to Rutherford, produces much more induced radio-activity in an unelectrified surface than in a positively electrified one.

The rate of diffusion through a porous plate of the gas obtained by bubbling air through distilled water containing a trace of radium is not the same as that of the gas got by bubbling through tap-water.

If the gas is confined in a closed space its radio-activity slowly diminishes. Mr. Adams found that the gas contained in a vessel of about 300 c.c. capacity lost when not exposed to an electric field about 5 per cent. of its activity in twenty-four hours; under a strong electric field the rate of loss was doubled. Water drawn from the tap and left exposed in a bucket for a fortnight gave off very little of the gas when subsequently boiled. I have not found any of the gas in any of the numerous samples of rain and surface water which I have tested.

Prof. Dewar (to whom I am greatly indebted for assistance and advice) was kind enough to subject the gas obtained by boiling the water to treatment by liquid air. Two samples were treated: one, containing about 80 litres of gas, obtained from the coppers of the Star Brewery, Cambridge, by the kindness of Mr. Armstrong (to whom I wish to express my thanks), was passed slowly through a bath of liquid air, and samples of the emergent gas collected; this on testing was found to have no radio-activity, though it was strongly radio-active before passing through the liquid air; it is evident, therefore, that at the temperature of liquid air the radio-active gas is frozen out. The other sample, of 20 litres, prepared in the laboratory was actually liquefied; the liquid was then allowed to boil away, the gas coming off at the commencement of boiling was collected, and also that coming off when the liquid had all but boiled away. On testing the samples for radio-activity the former was found to be slightly radio-active, but not nearly so much so as before liquefaction, while the second was extraordinarily radio-active, its activity being quite thirty times that of the original gas, thus showing, as we should expect from its great density, that the radio-active gas is much more easily liquefied than air.

The liquid obtained in the preceding experiment had a very strong smell of coal-gas. I must again express my thanks to Prof. Dewar and Mr. Lennox for their kindness in making these experiments.

A discharge tube was filled with strongly radio-active gas obtained as above, and the spectrum was most kindly investigated by Mr. Newall, who photographed it and measured the lines; no new lines were, however, discovered, the lines present being mainly those due to hydrocarbons.

I add a list of the various specimens of water I have examined; yes, means that the water contains the gas; no, that it does not.

Cambridge tap-water (yes). Rain water (no). Water from ditch round Botanical Garden (no). Water from Trinity College well, on the Madingley Road (yes). Water from artesian well in Mr. Whetham's garden, Chaucer Road (yes). Water from shallow well in same garden (no). Water from well at Star Brewery (yes). Artesian well in Trinity Hall Cricket Ground (yes). Artesian well at Girton (yes). Ely Town's water (yes). Birmingham Town's water (yes). Ipswich Town's water (yes).

In concluding this preliminary account I have much pleasure in thanking my assistant, Mr. E. Everett, for his help in this investigation.

GEOGRAPHICAL RESEARCH.

IN the course of his presidential address at the recent anniversary meeting of the Royal Geographical Society Sir Clements Markham, K.C.B., F.R.S., outlined a scheme, which is shortly to be put in operation by the Society, for the purpose of encouraging geographical research. The plan to be tried is the outcome of the afternoon meetings of the Society, started in 1894, for the reading and discussion of strictly scientific or technical papers. It is hoped that by the plan outlined in the subjoined extract from the president's address, the value of the afternoon meetings will be increased, and the scientific side of geography will be developed.

A permanent committee has been appointed to deal with this department of the work of the Society, to be called the "Research Committee." It will consist of those Fellows, taken from the List of Referees (which includes Fellows who have read papers, published books, or are known to have a special knowledge of any department of geography), who are most interested in, and best qualified to deal with, the subjects which are embraced in geographical research, as distinguished from exploration, in all its numerous branches. The committee will meet for the discussion of such results of investigation as may be brought before it; and the Council may be able to set apart a moderate sum each year for the purpose of encouraging such researches among the younger geographical aspirants.

Among the numerous lines that research may take, the following have been suggested:—

New methods of surveying, mapping, or computing.

Discussion of a definite problem of geomorphology (*e.g.* analysis of a river system or a coast-line).

Discussion of a definite problem of hydrography (*e.g.* circulation of water in a restricted sea area).

Discussion of a definite problem of meteorology (*e.g.* modifications of general weather conditions by local features).

Regional studies (*e.g.* synthesis of the geography of a county or of a natural unit such as the Fens).

Investigation of distribution (*e.g.* of some crop in relation to natural facilities and access to markets; of former forests in relation to existing boundaries; of village and town sites in a district).

Mapping of distribution of plant associations in a given area, or of a human disease in relation to climate and soil.

History of the map of some country (*e.g.* the British Isles).

Investigation of evidence of physical changes within historical times (*e.g.* the British coasts; the desiccation of continents).

Discussion of the relation of land forms to military movements in a selected area, or a chosen campaign.

Discussion of the relation of land forms to the distribution of man; to the distribution of animals in any area.

Geographical conditions affecting the development and colonisation of any given region.

Complete investigations from the geographical standpoint of a limited area of unexplored or partially explored territory.

There is still ample room for exploration and expeditions of discovery. We have scarcely yet laid down the great lines of the world's geography, and there is work for generations to come in filling in the details, though future exploration must become more and more exact and scientific in its characters. But we ought also to encourage research, for which exploration furnishes the raw material. By the plan now in contemplation, we shall develop the purposes of the List of Referees by constituting the Research Committee; and we shall develop further the object of the afternoon meetings by promoting research, the results of which will place the meetings on a more assured and regular system, by creating the necessity for their being more frequent and at fixed intervals.

NATURAL HISTORY NOTES.

WE learn from a contemporary that Mrs. Anderson has recently presented to the British Museum the whole of the zoological collections of her late husband, Dr. John Anderson. The great value of this collection is that it comprises all the original specimens on which Dr. Anderson based his great work on the mammals of Egypt. It also includes a collection made by Mr. T. Bent in the Hadramaut district of Arabia, and many specimens procured by Mr. H. F. Witherby in the Eastern Sudan—areas of which the fauna was but imperfectly represented in the Museum.

Visitors to the Natural History Museum will not fail to notice the fine new pair of giraffes from East Central Africa which have just been placed on the top of the flight of steps to the right of the Darwin statue. They replace a battered specimen which has been on exhibition since 1842. The male is presented by Mr. Rothschild and the female by Captain Powell-Cotton; both are mounted by Rowland Ward.

Bad Latin, as exemplified in scientific names, is, according to Prof. Cockerell (*Popular Science Monthly* for December, 1902), an evidence of too much narrowness and too little general culture among American naturalists. As regards the amount of zoological work done by the latter, it has been estimated that this should be about one-seventh of that of the whole world, and judging from the "Zoological Record," this estimate appears to be somewhat exceeded by the reality. This, however, according to the author, represents only a fraction of the work awaiting to be done if only the number of labourers were sufficient. "The Making of Biologists" forms the title of another article by the same author in the April number of the aforesaid serial, in which it is urged that, although naturalists are undoubtedly "born" rather than "made," yet that many are deterred by adverse circumstances from embarking on the career most suited to their abilities.

An English translation, by Mr. W. H. Clifford, of two memorials presented respectively in 1895 and 1896 to the Governor and Legislature of Para by Dr. H. Goeldi, directing attention to the destruction of white herons (egrets) and scarlet ibises on the Lower Amazon, has been recently published at Para. Whether protective legislation has been the result of these appeals is not stated, but from the details of the slaughter it is quite evident that such protection is urgently needed. In an appendix the author directs attention to the possibilities of egret-farming, and states that this has been established with successful results in Tunis. Egret-plumes are worth more than their weight in gold, and the profits from a "farm" of this nature, where the feathers are cut from the birds at the proper season, ought to be very large.

In the May number of *The Field Naturalists' Quarterly* the editor directs attention to the great increase in the membership of field clubs and societies, and the multiplication of such institutions all over the country, as satisfactory proof of the awakening of interest in natural history. Among the articles in this number are one, by the Rev. G. C. Bateman, on newts in spring, and a second, by Mr. J. R. B. Masefield, on the white cattle of Chartley, Staffordshire, both illustrated. In the latter the author adopts the view that British white park cattle are the descendants of white sacrificial cattle introduced by the Romans, ignoring the close relationship between the Chillingham herd and the old Pembroke breed so strongly insisted on in Low's "British Domesticated Animals." Apparently he has not visited the domesticated series in the Natural History Museum, or, at all events, has not read the descriptive labels.

Unusual interest attaches to an article by Prof. G. H. Parker on the hearing of fishes in the March number of the *American Naturalist*. After mentioning that the sense of hearing is restricted to a small number of animal groups—notably insects and vertebrates—and is consequently a special development, the author refers to recent investigations which have been thought to prove that the ear of fishes is not connected with the auditory function. This view he believes to be incorrect, and he is convinced that fishes do hear sound-waves communicated through water. The intimate connection between sound and touch is strongly insisted upon, and it is shown that fishes—and, to a certain extent, amphibians—exhibit in a marked degree the connection between the tactile and auditory senses by means of the lateral line system. The three sets of sense-organs under consideration—namely, the skin, the lateral line, and the ear—"may be regarded as having slightly different kinds of stimuli; the skin being affected by surface-waves and currents; the lateral line organs by slight inaudible movements of the whole mass of water; and the ears by the still more delicate vibrations of water particles, sound. . . . Hearing, then, is a most delicate form of touching, and the organ of hearing has developed late in the animal series because its processes are not original, but are derived from those of the more primitive sense, touch."

Indian Museum Notes, as exemplified by vol. v. No. 3, maintains its high reputation as a chronicle of the economic entomology of the Indian Empire, this part containing five original communications from writers who are not members of the museum staff, and an important series of notes by the latter. In the first category Mr. E. P. Stebbing discusses the insect pests of the sugar-cane, while among the second reference may be made to investigations which have been undertaken in connection with insects found in drinking water. It appears that in December, 1900, the filtering beds of the Calcutta water-supply were swarming with a dipterous larva, which on examination proved to belong to the midge *Chironomus cubiculorum*, while in the following year the lake in the city of Colombo, Ceylon, was found to be so infested with the larva of a member of the same genus as to be dangerous to health. Special means for exterminating this "lake-fly" are suggested by the Government entomologist.

We learn from the April number of its official organ, the *Emu*, that the Australian Ornithologists' Union has successfully completed the first year of its existence, and that its work is steadily progressing. The excellence of its journal speaks for itself, and it may be regarded as a proof of its success that the present part contains a beautiful coloured plate, by H. Gronvöld, of blue wrens (Malurus). Perhaps the most noteworthy feature of the work of the Australian O. U. relates to the protection of indigenous birds, and the prevention of the trade in so-called "osprey" plumes. It is most satisfactory to learn that action has been taken for the better protection of the colonies of egrets in Victoria, which were so ruthlessly attacked for the sake of their plumes, with the result that the Government has decided to protect them throughout the year. Suggestions have been forwarded to the Government of Queensland with regard to the advisability of reserving certain islands for the peculiar Torres Strait or nutmeg pigeon, and efforts have been made to secure one of the Victorian lakes as a breeding-reserve for wild-fowl. The Tasmanian Government has also been approached with a view of preventing the wholesale destruction of the eggs of the Cape Barren geese breeding in certain islands of Bass Strait, since it is feared that the species is in danger of extermination. Action has likewise been taken to ensure the protection of the colonies of petrels, or "mutton-birds," breeding on Phillip Island.

"Os Mosquitos no Pará" forms the title of a pamphlet by Dr. E. Goeldi, recently issued by the Government Press of Para.

To the *Journal* of the Asiatic Society of Bengal (vol. lxxi. No. 2) Mr. K. B. Sanyal contributes some observations on the habits of the orang-utan in captivity.

We have received the report of the Rugby School Natural History Society for 1902, which contains a prize essay on the Tertiary rocks of Hampshire, by Mr. H. A. Ormerod, and shows that the Society continues to prosper.

In the *Boletin* of the Agricultural Commission on Parasites of Mexico (vol. i. No. 8), Prof. T. D. A. Cockerell describes a new scale-insect (*Neolecanium herrerae*) infesting agave; while in the February number of *Psyche* the same writer records several new races of various species of the same group belonging to the genus Eulecanium.

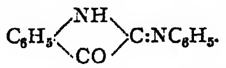
The *Boletim* of the Para Museum contains, among other papers, a list of the birds of Amazonia, extracted from the British Museum Catalogue, and a descriptive synopsis of the lizards of Brazil, both by Dr. E. Goeldi. Botanists will be interested in a paper on the "rubber-trees" of Amazonia, by Dr. J. Huber, as well as in a fifth instalment of the same author's account of the Amazonian flora.

A NEW SYNTHESIS OF INDIGO.

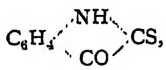
An important new synthesis of indigo is described by Dr. T. Sandmeyer in the April number of the *Zeitschrift für Farben- und Textil-Chemie*. The starting point for the synthesis is thiocarbanilid, $CS(NH.C_6H_5)_2$, which is converted in one operation by the simultaneous action of white lead and potassium cyanide into the hydrocyanide, $C_6H_5.N:C(CN).NH.C_6H_5$, of carbodiphenylimide. This compound is changed by the action of yellow ammonium sulphide into the thioamide,

$$C_6H_5.N:C(CS.NH_2).NH.C_6H_5,$$

which, when stirred into warm sulphuric acid, undergoes condensation, and yields an α-isatinanilide,



The anilide is converted directly into indigo when dissolved in alcohol and reduced with ammonium sulphide, but the indigo separates in glistening crystals which cannot easily be reduced by the ordinary methods, and so is unsuitable for commercial use. A better method, and one which renders it unnecessary to separate the isatinanilide from the sulphuric acid used in its preparation, consists in allowing the acid solution to flow into ice-water simultaneously with a solution of sodium sulphide, when the anilide is converted into thioisatin,



which is thrown down as a bulky precipitate. In order to prepare the indigo it is now only necessary to make the precipitate into a thin paste and mix it with a little alkali, when the thioisatin rapidly decomposes into indigo and sulphur. The sulphur is removed by extracting with carbon disulphide, and the indigo is left in the form of light, dark-blue blocks, which readily crumble when rubbed between the fingers, and can be made into a uniform paste which is easily reduced to indigo-white. The patents are held and are being worked by J. R. Geigny, of Basle, and the process may prove to be a formidable rival not only to natural indigo, but also to the synthetical process employed by the Badische Anilin- und Soda-Fabrik.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The 249th meeting of the Junior Scientific Club was held on May 20. Mr. H. S. Souttar gave an exhibit of an automatic method of drawing capillary tubes intended for use in the capillary electrometer. Mr. S. A. Ionides read a paper on "Mining in Cornwall," in which he gave an account of the methods employed for raising and washing the tin ores.

CAMBRIDGE.—Mr. Andrew Graham, who has for nearly forty years held the office of chief assistant at the observatory, and is known to astronomers as the discoverer of *Metis*, is retiring at the age of eighty-eight. It is proposed to assign him a pension of 200*l*. a year.

The use of the Senate House has been granted to the local committee of the British Association for the meeting to be held in Cambridge next year.

LORD KELVIN and Lord Lister are to receive the honorary degrees of doctor of science from the University of Wales next November.

MR. W. M. CHILDS, vice-principal of University College, Reading, has been elected principal of the College in succession to Mr. H. J. Mackinder, who resigns office in September next.

IT is stated by the *Electrician* that a donation of nearly 40,000*l*. has been promised by Lord Iveagh to Trinity College, Dublin, with the object of building and equipping scientific laboratories.

THE Liverpool University Bill was, on Tuesday, reported for third reading by Lord Morley, Chairman of Committees of the House of Lords. The object of the Bill is to separate University College, Liverpool, from the Victoria University, and to merge it into the University of Liverpool.

THE annual report of the Royal Agricultural Society, which was adopted at the general meeting held on May 22, states that with the view of bringing before the public the general characteristics of the teaching now provided at agricultural colleges, and of directing attention to the Society's own share in this work as a national examining body, the council has decided to organise an agricultural education exhibition as a new feature of its annual show.

IN his recent paper read at a meeting of the Society of Arts Mr. G. T. Morrison gave a clear and useful account of the modern methods of construction of maps and charts. His descriptions of orthographic, stereographic, Mercator's, gnomonic and elliptical projections should prove of great assistance to teachers who wish to explain the methods employed to make maps, which either give good general ideas of the appearance of the whole or of parts of the earth, or retain some one property of the sphere at the expense of disregarding the others. Mr. Morrison thinks that for the purpose of teaching geography a projection based, not on any distinct mathematical rule, but on a system of compromise, is on the whole the best—one, for example, on which the meridians and parallels are spaced at equal distances throughout.

ARRANGEMENTS have been made for an allied colonial universities dinner and conference to be held early in July. The conference will be held on July 9 at the rooms of the Royal Society, Burlington House (by permission of the president), to discuss the question of the coordination of university education throughout the King's dominions, and the development of post-graduate courses in applied science. It is expected that an Imperial council will be formed to deal permanently with these interests. The dinner will be held on Friday, July 10, at the Hotel Cecil. The Lord Chancellor and other statesmen, many high public officials, representatives of colleges and universities in the United Kingdom and the colonies, and several distinguished men of science are expected to be present. Graduates and undergraduates of colonial universities wishing to attend the dinner, or to take part in the conference, are requested to write as soon as possible to Mr. C. Kinloch Cooke, hon. sec., 3 Mount Street, London, W.

THE annual catalogue, 1902–3, of the Massachusetts Institute of Technology at Boston gives very full particulars of the numerous courses of instruction in connection with the institute, a clear plan of the extensive buildings, a register of graduates, and other interesting details. The tuition fee for regular students is 50*l*. per annum, for half a year or any shorter period the fee is 30*l*. Special students pay, in general, the full fee; but when a few branches only are pursued and the time required for instruction is limited, applications for a reduction in the fees are considered. Regular students whose financial necessities are such as to prevent their continuance at the institute are encouraged to apply for aid to the scholarship committee of the faculty. Students may conveniently live in any of the nearer cities or towns, since the hours of the institute are from 9 to 5. The cost of board and rooms in Boston and the neighbouring towns need not exceed from thirty shillings to two pounds a week. The cost of books and material varies from five to seven pounds a year.

THE second clause of the London Education Bill, referring to the constitution of the education committee was withdrawn by the Government on Monday. In its original form the Bill provided for the appointment of thirty-one representatives of the borough councils upon the committee. This number was reduced to twelve in Committee of the House of Commons last week, but the compromise pleased nobody, so the whole clause, with its restrictions upon the local authority with regard to the constitution of the Education Committee, has been omitted from the Bill. By this action the London County Council, so far as the constitution of its education committee is concerned, is placed in precisely the same position as other local authorities brought into being by the Act of last year. The Council will frame a scheme for itself, just as other county councils have done, or are doing, and under the same conditions.

On Tuesday the Bill passed through Committee, but the third clause was greatly modified. In its altered form the clause provides for a body or bodies of management in each borough, constituted so as to include one-fourth members nominated by the County Council, and three-fourths by the borough council. The measure, as passed, does not include the clause giving the borough councils the power of appointing and dismissing teachers.

SCIENTIFIC SERIALS.

Transactions of the American Mathematical Society, vol. iv. No. 2 (April).—G. H. Darwin, approximate determination of the form of Maclaurin's spheroid.—H. S. White, on twisted cubics that have a directrix.—L. Heffter, line-integrals in n-dimensional space.—E. Kasner, the generalised Beltrami problem concerning geodesic representation.—G. A. Miller, on the holomorph of a cyclic group.—J. L. Coolidge, quadric surfaces in hyperbolic space.—A. Loewy, on the reducibility of real groups of linear homogeneous substitutions.—W. B. Ford, on the possibility of differentiating term by term the developments of an arbitrary function of one real variable in terms of Bessel functions.—E. J. Wilczynski, on a certain congruence associated with a given ruled surface.—J. Westlund, on the class-number of the cyclotomic field $k(e^{2\pi i/p^n})$.

Bulletin of the American Mathematical Society (2) vol. ix. No. 8 (May).—E. H. Moore, presidential address on the foundations of mathematics.—C. J. Keyser, concerning the axiom of infinity and mathematical induction.—E. R. Hedrick, review of R. Fricke's treatise on the differential and integral calculus.

SOCIETIES AND ACADEMIES.

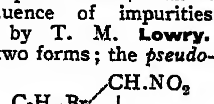
LONDON.

Royal Society, May 7.—"Experiments in Hybridisation, with Special Reference to the Effect of Conditions on Dominance." By L. **Doncaster**, B.A., King's College, Cambridge. Communicated by Dr. S. F. Harmer, F.R.S.

Describes experiments on hybrid Echinoid larvæ, made to determine whether the dominance of a character is influenced by the condition of the genital cells at the time of fertilisation. It is concluded that there is no evidence that this is the case, and that the seasonal changes observed in the larvæ are due to difference in temperature.

May 14.—"A New Class of Organo-Tin Compounds containing Halogens." By William J. **Pope**, F.R.S., Professor of Chemistry, Municipal School, Manchester, and Stanley J. **Peachey**.

Chemical Society, May 7.—Prof. H. McLeod, F.R.S., vice-president, in the chair.—It was announced that the council at its meeting that day had awarded the Longstaff medal to Prof. W. J. **Pope**, F.R.S., for his researches on the stereochemistry of compounds of elements other than carbon.—The following papers were read:—The action of ammonia and organic bases on ethyl esters of olefinedicarboxylic and olefine-β-ketocarboxylic acids, part ii., by S. **Ruhemann**.—Spontaneous decomposition of nitrocamphor, by T. M. **Lowry**. A quantity of nitrocamphor, prepared in 1898 and purified by recrystallising once from alcohol, was found to have undergone spontaneous change into a sesquicamphorylhydroxylamine, identical with that prepared from camphoryl chloride and camphoryloxime.—β-Bromo-α'-nitrocamphor- and β- and π-bromocamphoryloximes. The influence of impurities in conditioning isomeric change, by T. M. **Lowry**. β-Bromo-α'-nitrocamphor exists in two forms; the *pseudo*-form,



separates from solutions of the nitro-compound in benzene or ethyl acetate. The normal form was not isolated. A mixture of the two forms, obtained by crystallising from hot alcohol or acetic acid, softened at 100°, melted without decomposition at about 114°, and remelted sharply at 100°; the latter is therefore the temperature at which the solid *pseudo*-form is in stable equilibrium with the liquid mixture. Freshly prepared solutions of β-bromo-α'-nitrocamphor exhibit the phenomenon of mutarotation. A solution in benzene of the *pseudo*-form is at first almost inactive, but in the course of two or three days the specific rotatory power becomes constant and equal to $-80°$. The change of rotatory power is not spontaneous, but is conditioned by the presence of traces of impurity. This fact shows that, even when both isomerides are present in solution, equilibrium between them is only established in presence of a trace of a catalytic agent, probably an alkali. These phenomena are closely analogous to Baker's observations on the union of hydrogen and oxygen, and are directly opposed to Laar's hypothesis of "tautomerism."—The electrolytic reduction of pheno- and naphtho-morpholones, by F. H. **Lees** and F. **Shedden**. Attempts were made by electrolytically reducing aromatic morpholones in sulphuric acid solution to produce aromatic morpholines possessing physiological properties similar to those of morphine; the morpholone ring, however, usually undergoes secondary decomposition.—The coloured constituents of *Butea frondosa*, by E. G. **Hill**. The dried and fresh flowers of *Butea frondosa*, used in India for the preparation of a somewhat fugitive yellow dye, contain fisetin and different anhydrides of a tannic acid.—Butein. A preliminary notice by (the late) J. J. **Hummel** and A. G. **Perkin**. Butein, the colouring matter of the flowers of *B. frondosa*, described by Hummel and Cavallo in 1894, probably exists in two modifications which, on fusion with alkali, give resorcinol and protocatechuic acid. The tinctorial properties of butein closely resemble those of benzylideneanhydroglycogallol, to which it is possibly allied.—The relative affinities of polybasic acids, by H. M. **Dawson**.—The chemical dynamics of the reactions between chlorine and benzene under the influence of different catalytic agents and of light, by A. **Slator**. With a large excess of the hydrocarbon, the relative amounts formed of the two chief products chlorobenzene and benzene hexachloride depend on the conditions of the experiment. The velocity of these reactions, especially under the influence of different catalytic agents, has been measured under various conditions. Under the influence of light without catalysts, the addition reaction alone occurs; under conditions of equal illumination, the velocity of this change is found to be proportional to the square of the chlorine concentration.—The diazo-reaction in the diphenyl series. Part i. On dianisidine and 3:3'-dichlorobenzidine, by J. C. **Cain**. On heating aqueous solutions of the diazonium salts prepared from dianisidine and 3:3'-dichlorobenzidine, dark-coloured, insoluble, infusible compounds which appear to be quinones are obtained instead of the expected dihydroxy-derivatives.

Linnean Society, April 16.—Rev. T. R. R. Stebbing, vice-president, in the chair.—Dr. G. **Henderson** exhibited a coloured sketch of a withered leaf of *Quercus incana*, Roxb., and of slugs found amongst the dead leaves. The drawing of the mollusc and leaf was to show their strange resemblance in colour and outline. These slugs are common at Dalhousie in the Punjab, on ground which is always covered with these withered leaves. A few black slugs were to be found with the light-brown specimens, and whilst the latter escaped the notice of birds, the former were taken.—On some points in connection with the ordinary development of Vaucheria resting-spores, by Dr. H. C. **Bastian**, F.R.S. In 1891 the author had some spores of Vaucheria under observation in a bottle loosely covered with a screw-cap, and after a few weeks these spores were found to be germinating and emitting filaments. In 1902 the experiments were repeated on *Vaucheria racemosa*; material was kept in a shallow dish, and a few days later the spores were transferred to a stoppered bottle; another portion was put into a tumbler, loosely covered to exclude dust. Within seven weeks the bottled specimens germinated, a process which did not take place in those in the tumbler for some time later. Special attention was drawn to the pigment-granules, to be regarded as refuse-products left over during the molecular transformation that the spore has undergone in becoming decolorised; they are heaps of fine granules, without any bounding membrane. These pigment-heaps pass into the filament as spheres with a sharply-defined outline, or else press together in compressed forms. Slight to-and-fro movements were detected in them. One pigment sphere

was seen to be encysted, outside the filament from which it had been liberated. These forms resemble Amœbæ or the simplest form of Actinophrys, but seem to be so heavily charged with indigestible matter as to have but a slender chance of further development.—On the labial and maxillary palpi in Diptera, by Mr. **Wesché.** The author set out to homologise the mouth-parts of Diptera with the typical insect mouth-part, and stated that in the Muscidæ the mandibles are embedded in the dorsal side of the labium. The maxillary palpi, galæ, and laciniæ are aborted, but the cardines and stipes remain; the latter parts bear minute rudiments of the maxillary palpi. The palpi present are labial. In the Syrphidæ and Empidæ the mandibles are similarly placed, but the maxillæ are represented by the laciniæ, the *palpi*, cardines, stipes, and palpifers. The labial palpi are aborted. The author formulated a rule, that *the maxillary palpi when present in Diptera are always in contact with the upper part of the cardines, the stipites.*—Observations on fresh-water rhizopods, with some remarks on their classification, by Prof. G. S. **West.** The author states that whilst examining material from the western districts of the British Islands, interesting rhizopods came under notice, concerning four of which he could find no previous mention. Two of these are species of Hyalosphenia, one is a species of Sphenoderia with a prettily constructed shell, and another is a curious nude form referable to Cienkowski's genus Nuclearia. With regard to the distribution of rhizopods in the west of Scotland, the noticeable feature is the relative scarcity of these animals in the Outer Hebrides as compared with their occurrence on the Scottish mainland. Full reasons are given for the establishment of the Vampyrellidæ as a distinct order of fresh-water rhizopods, to include the genera Vampyrella and Nuclearia.

PARIS.

Academy of Sciences, May 11.—M. Albert Gaudry in the chair.—New studies on a law relating to the electromotive forces developed by the reciprocal action of saline solutions, by M. **Berthelot.** If E is the E.M.F. developed by the action of an acid on a base, and the E.M.F. developed by the action of the corresponding salt on the acid be ϵ_1 and on the base ϵ_2, then the author has established experimentally the law $E=\epsilon_1+\epsilon_2$.—On the traces of the Lutitian sea in the Soudan, by M. **de Lapparent.** Fossils found by French officers in the Soudan, including a new species of Plesiolampas, undoubtedly belong to the Middle Eocene. It may thus be considered as certain that the Lutitian sea, traces of which have been already made out with certainty in the neighbourhood of Dakar, spread out into the heart of the Soudan.—On the existence of radiations capable of passing through wood and certain metals in the rays from an incandescent mantle, by M. R. **Blondlot.** The radiations were detected by their action on very small sparks, the arrangement of the apparatus being similar to that previously described by the author in connection with the radiation of an X-ray focus tube, and also by their photographic action. They resemble in some respects the rays of long wave-length discovered by Rubens, in that both are emitted by an incandescent mantle, and are stopped by water. On the other hand, the Rubens rays are stopped by metals, which are traversed in thin layers by the radiations now described.—On a class of differential equations reducible to Bessel's equation, by M. Alexander S. **Chessin.**—On the zeros of monodrome functions, or with ν branches, by M. Edmond **Maillet.**—On thermomagnetic effects in bismuth-lead alloys, by M. Edmond **van Aubel.**—On the modulus of traction and the coefficient of expansion of vulcanised indiarubber, by MM. **Bouasse** and **Carrière.** In reasoning from the equation $dL=\alpha.dt+\epsilon dP$, dL is usually taken as an exact differential. This, however, is far from being the case; the coefficients α and ϵ are very variable, since they depend upon the previous history of the specimen under examination. It is shown that the value of these coefficients may be made to vary between wide limits by varying the cycle of operations, and it is not possible on theoretical grounds to give the preference to any one of these.—On the electrolysis of alkaline sulphides, by MM. André **Brochet** and Georges **Ranson.** It has been shown in previous work that the final product of electrolysis is sulphate, with an intermediate formation of thiosulphate. Working in concentrated solution at 50° to 70°, the process is entirely different, sulphur being deposited at the anode and sodium at the kathode, hydrogen and sodium hydroxide appearing in the latter case as the secondary products. The sulphur formed dissolves in the sulphide, giving polysulphides.—On benzene-azo-orthobenzyl alcohol and on its transformation into phenylindazol and azodiphenylmethane, by M. P. **Freundler.** The alcohol is easily obtained by the condensation of nitrosobenzene with *o*-aminobenzyl alcohol in presence of alcohol and acetic acid.—Organometallic derivatives of aromatic hydrocarbons containing two halogen atoms in the nucleus, and their interaction with iodine, by M. F. **Bodroux.** The dihalogen derivative reacts with magnesium to give $X.C_6H_4MgX$, and this, with iodine, forms the mixed halogen compound $C_6H_4.XI$. The reaction appears to be general, and has been extended to naphthalene compounds.—On the methylation of ethyl glutaconate, by M. E. E. **Blaise.**—The migration of the methyl group in the camphor molecule, by MM. G. **Blanc** and M. **Desfontaines.**—On the successive action of acids and soluble ferments on polysaccharides of high molecular weight, by MM. Em. **Bourquelot** and H. **Hérissey.**—The diastatic hydrolysis of salol, by M. Emm. **Pozzi-Escot.** The hydrolysing ferments of plant seeds, which act easily upon the esters of the fatty acids, are nearly without action upon the phenol ethers.—On the law of electrical excitation in some invertebrates, by M. and Mme. L. **Lapicque.** It is shown that the law enunciated by Weiss is only an approximate one; the establishment of a more correct formula is reserved for a later communication.—Excretion and phagocytosis in Onychophores, by M. L. **Bruntz.**—On the absorption of the tetanic antitoxin; the immunising action of dry antitetanic serum, by M. A. **Calmette.**—On the reversibility of lipolytic actions, by M. Henri **Pottevin.** If oleic acid be added to a glycerol extract of the pancreas, partial esterification takes place; starting with mono-olein, a partial hydrolysis occurs, and in both cases there is a final state of equilibrium produced, characterised by the same value for the ratio between the weights of the free and combined acid.—The influence of formaldehyde on the growth of white mustard, by MM. **Bouilhac** and **Giustiniani.** When, owing to insufficient light, the chlorophyll assimilation of the plant is rendered difficult, formaldehyde may serve as a plant food, but if the intensity of the light is diminished below a certain amount, this assimilation ceases, the formaldehyde exerts a poisonous effect, and all the plants die.—How far is it possible to modify the habits of plants by grafting? by M. Lucien **Daniel.**—On the spontaneous combustion of balloons, by M. W. **de Fonvielle.** Certain explosions of balloons would appear to be traceable to electrical effects, which determine a spark at the moment the aëronaut grasps the valve rope. As a precaution, the use of indiarubber gloves is suggested in stormy weather.—On the culture of the truffle, by M. Émile **Boulanger.**

May 18.—M. Albert Gaudry in the chair.—The statistics of the minor planets. The distribution of the elements, taking the aphelion longitude as argument. The comparison of the minor planets with short period comets, by M. O. **Callandreau.**—The measurement of the velocity of ships at sea, by M. E. **Guyou.** A return to the oldest form of line log is suggested, with certain modifications. The float is replaced by a light calico bag containing a little sand, the resistance of which is sufficient to form a very satisfactory fixed point. The line is looped in coils and not on a reel, and is fitted with a simple electrical indicator. An accuracy of 1 per cent. is obtainable with this arrangement.—On the distribution of matter on the surface of the earth, by M. G. **Lippmann.**—The conductivity and residual ionisation of solid paraffin under the influence of the radium radiation, by M. Henri **Becquerel.** It is easily shown that solid paraffin becomes a conductor whilst under the action of the radium emanation, and this is not immediately lost on the removal of the radium, but, although diminishing rapidly, is still appreciable during about half an hour.—The preparation and properties of cæsium ammonium and rubidium ammonium, by M. Henri **Moissan.** These substances were obtained by the action of liquid ammonia on the metals, the methods employed being similar to those previously described for sodium, potassium, and lithium. Cæsium ammonium is crystal-

line, and takes fire at once in the air. Its analysis gave figures corresponding to the formula $CsNH_3$, and the rubidium compound has an analogous composition. The solutions of these substances in liquefied ammonia have been utilised for the production of the carbides of cæsium and rubidium.—Secular perturbations of the first degree with respect to the eccentricity, by M. Jean **Mascart**.—On the visibility of the eclipsed lunar disc during the second half of the eclipse of April 11–12, by M. **Amann**. The peculiar and exceptional visibility of the eclipsed portion of the moon's disc was confined to the second part of the eclipse.—On the decomposition of a linear substitution, real and orthogonal, and on a product of inversions, by M. Léon **Autonne**.—On the value of averages in meteorology, and on the variability of temperatures in France, by M. Alfred **Angot**. It is pointed out that the arithmetical mean of a series of experimentally observed numbers is only the most probable result if the causes of error are purely accidental, and that this latter condition does not necessarily hold in meteorological observations. Observations taken in France over a period of fifty years are discussed with the view of determining between what limits this condition is satisfied.—On the electrical conductivity of selenium in the presence of bodies treated with ozone, by M. Edmond **van Aubel**. Substances after treatment with ozone, and which are capable of being attacked by it, increase the electrical conductivity of selenium, the rate of return to the original resistance being extremely slow.—On the transmission of photographs by means of a telegraph wire, by M. **Korn**. The image is produced photographically upon a rotating plate by means of the light from a vacuum tube, and the latter is worked by high frequency Tesla currents, governed by a selenium cell at the transmitting end of the wire. The rate of transmission is slow, owing to the inertia of the selenium.—On the theory of coloured indicators, by M. P. **Vaillant**. From a quantitative study of the colour of solutions of paranitrophenol and its salts, the conclusion is drawn that the definition of an indicator given by Ostwald and Nernst is incomplete.—Electrolysis of the sulphides of the alkaline earths, by MM. André **Brochet** and Georges **Ranson**. In concentrated solutions, electrolysed at 60°, sulphur, baryta and hydrogen are produced, indicating that the primary products are sulphur and barium. There is no evidence of the production of any oxidation products.—On a new method for the estimation of the halogens in organic compounds, by MM. H. **Baubigny** and G. **Chavanne**. The substances are oxidised by chromic acid mixture in presence of a silver salt; chlorine and bromine are set free, whilst iodine is completely converted into iodic acid. Test analyses of several iodine compounds prove the accuracy and convenience of the method.—The action of ethyloxalyl chloride on mixed organo-magnesium compounds, by M. V. **Grignard**.—The action of the bases of the alkaline earths upon the salts of pyrogallol-sulphonic acids, by M. Marcel **Delage**.—A new method for the estimation of glycerol, by M. A. **Buisine**. The process is based upon the production of a mixture of hydrogen and methane by the interaction of glycerol and a mixture of potash-lime and caustic potash at 350°. It has the advantage of requiring a very small quantity of material, and is very rapid.—A new test for lead and manganese, by M. R. **Trillat**.—On the comparative physiology of the two kidneys, by M. J. **Albarran**. In unit time, the two kidneys secrete different quantities of urine of different composition. There is a partial compensation in that the kidney producing the larger quantity of urine secretes a less concentrated liquid.—On a point in the anatomy of some Oculininæ and Pæciloporinæ, by M. Arm. **Krempf**.—On a cause of variation in fossil fauna, by M. H. **Douvillé**.

DIARY OF SOCIETIES.

THURSDAY, MAY 28.

ROYAL SOCIETY, at 4.30.—On the Bending of Waves round a Spherical Obstacle: Lord Rayleigh, O.M., F.R.S.—Sur la Diffraction des Ondes Électriques à propos d'un Article de M. Macdonald: Prof. H. Poincaré, For.Mem.R.S.—On the Theory of Refraction in Gases: G. W. Walker.—An Analysis of the Results from the Kew Magnetographs on *Quiet* Days during the Eleven Years 1890 to 1900, with a Discussion of Certain Phenomena in the Absolute Observations: Dr. C. Chree, F.R.S.—On a Remarkable Effect produced by the Momentary Relief of Great Pressure: J. Y. Buchanan, F.R.S.—Evolution of the Colour-Pattern and Orthogenetic Variation in Certain Mexican Species of Lizards with Adaptation to their Surroundings: Dr. H. CONTENTS.

THURSDAY, JUNE 4, 1903.

INFINITE SERIES.

Théorie élémentaire des Séries. Par Maurice Godefroy: avec une Préface de L. Sauvage. Pp. viii + 268. (Paris: Gauthier-Villars, 1903.) Price 8 francs.

INFINITE series present themselves in mathematics in different contexts, serve different purposes, and admit of different interpretations. The simplest case is when, from a numerical sequence $(u_1, u_2, u_3, \ldots)$, we derive the series

$$u_1 + u_2 + u_3 + \ldots$$

which we may denote by Σu. It is assumed that there is a rule for calculating u_n when n is assigned; if we write s_n for $u_1 + u_2 + \ldots + u_n$, there exists a sequence $(s_1, s_2, s_3, \ldots)$ and we may, in fact, regard Σu as being, in a manner, a symbolical expression of this sequence. When we say that Σu is convergent and its sum is s, what is really meant is that the sequence (s_n) converges to the limit s.

To Cauchy and Abel is mainly due a strict theory of such arithmetical series. They showed that, whether its terms are real or complex numbers, a series of this sort may be divergent, indeterminate, or convergent; and that series which are absolutely convergent may be combined by processes which we may call addition, subtraction, multiplication, and division. There is one part of this theory which, even yet, is not always made so clear as it might be. Suppose that we have two sequences (u_n), (v_n) of such a character that every element u_p of the one occurs as an element v_q in the other, and conversely; that this is a (1, 1) correspondence, that is to say, that each element of one sequence is associated with one, and only one, of the other; and, finally, that when p is finite, q is also finite, and conversely. In this case we may call (v_n) a permutation of (u_n). When Σu_n is absolutely convergent, so is Σv_n, and the sums of these two series are the same; it is this property, really, that makes absolutely convergent series so easy to work with. Properly speaking, a series is distinct from its permutations; but in the case of an absolutely converging series this distinction may be ignored. It is a remarkable fact that a series and one of its permutations may both converge and have different sums. It is rather unfortunate that the phrase "changing the order of the terms in a series" is still used; it is certainly best to regard a series as defined, not merely by its terms, but by the order in which they are written.

After discussing this arithmetical theory, M. Godefroy proceeds to the next simplest case, when the terms of the series are functions of a variable x which is supposed to assume numerical values. Here the distinction between uniform and non-uniform convergence appears, a distinction first emphasised by Stokes and Seidel. In the sequence (s_n) derived from a convergent series of this kind, the index n for which s_n first differs from the sum of the series by less than an assigned quantity h is, in general, a function of x as well as of h; so that for particular values of x and their immediate neighbourhood n may be enormously large even for values of h which, though small, are not infinitesimal; accordingly the series is no longer available for practical calculation. At such places the convergence ceases to be uniform; the convergence is uniform wherever it is possible to assign, in terms of h but *not* of x, a value of n for which $|s_n - s| < h$.

Of course, the most important series of this class are power-series, and in his third chapter M. Godefroy deals with them at some length. On pp. 67–69 he gives Dirichlet's proof of Abel's fundamental theorem that when a power-series is convergent its value at the boundary of its circle of convergence is the limit of its value as x approaches the boundary. To learn to appreciate the necessity for proving this theorem is a good exercise for the mathematical student; it looks so obvious and is yet so far from being a truism.

The remaining three chapters are on the exponential function, the circular functions, and the gamma-function respectively. The noteworthy features are that sin x, cos x are defined by power-series, that the transcendence of e is demonstrated, and that the properties of the gamma-function are deduced, after the manner of Gauss, from the product $\Pi(n,x)$. M. Godefroy points out that Weierstrass's formula

$$\frac{1}{\Gamma(x)} = xe^{Cx}\Pi\left(1+\frac{x}{n}\right)e^{-x/n}$$

was explicitly given in 1848 by F. W. Newman (*Camb. and Dubl. Math. Journ.*, vol. iii. p. 59).

The final chapter is the one which presents most novelty in the shape of actual results; thus, besides the series of Stirling, we have various interesting formulæ due to Prym, Hermite and others. But M. Godefroy's style and method will attract the reader's attention throughout; he combines simplicity with rigour, and is neither dry nor diffuse. His work is one which may be cordially recommended, especially to mathematical students; not the least of its merits is its excellent bibliography, which is just what a treatise of this sort should contain.

M. Godefroy does not explicitly introduce the complex variable, but it is easy to complete the chapter on power-series so as to make its results apply when x is complex. Thus we have, on the whole, a discussion, with illustrations, of numerical series, and of power-series which define functions of a variable within a circle of convergence.

Incidentally, we have examples of two other kinds of series. Stirling's formula is the classical example of a series which does not define a function, but which, while ultimately divergent, serves to calculate the numerical value of a function very exactly for any sufficiently large value of x. Such asymptotic series have been recently studied by Poincaré, Borel and others, and their properties are no longer a mystery.

Again, Lambert's series

$$\frac{x}{1-x} + \frac{x^2}{1-x^2} + \ldots + \frac{x^n}{1-x^n} + \ldots$$

is an example of a series which serves for enumeration. If each term is expanded in powers of x, and the result collected, we get $\Sigma\psi(n)x^n$, where $\psi(n)$ is the number of ways of solving $n = \delta\delta'$ with integral values of δ, δ', the order of δ, δ' being taken into account except when they are equal. Thus $\psi(n) = 2$ when n is prime, but not

otherwise. So long as $|x| < 1$, Lambert's series defines a function of x; calling this $f(x)$, a prime number p is distinguished by the fact that it makes

$$D_x{}^p{}_r(x) = 2p(p!)$$

when $x=0$. There are many remarkable instances of arithmetical truths derived by constructing an enumerative series (purely symbolical, in the first instance) and then investigating its properties as a function of x. Ultimately, of course, the results obtained must depend upon purely arithmetical considerations; but transcendental analysis supplies, in such cases, a kind of machine, by which, with slight effort, theorems are verified, or even suggested, although the proof of them by strictly arithmetical methods may be very difficult. Whether Lambert's series can be used in this way to simplify the problem of the frequency of primes still remains an open question. G. B. M.

A PLEA FOR INTERACTION.

Geist und Körper, Seele und Leib. Von Ludwig Busse. Pp. x+488. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1903.) Price 8.50 marks.

IN this book the author aims at finally establishing a doctrine of "interaction." Previous expositions in less comprehensive form have already been criticised by eminent writers; to these objections the author now replies. The result is a veritable encyclopædia of views on this question; authors of all nationalities are here cited to defend themselves against criticisms which are throughout shrewd and relevant. In the mass of material the author's particular theory is apt to be obscured; a strictly methodical procedure has to some extent obviated this defect. After a refutation of materialism, adequate for its purpose as *entrée*, we come to the *pièce de résistance*, entitled "Parallelism or Interaction?" Here parallelism is discussed under the heads modality (is parallelism a metaphysical doctrine or merely a hypothesis?), quantity (must it be partial or complete?), and quality (materialistic, realistic-monistic, idealistic-monistic, and dualistic forms). From this catalogue there finally emerge as "valid forms" only the complete, the realistic-monistic, the idealistic-monistic, and the dualistic forms. The method of criticism employed is called by the author "immanent." Internal dissensions reduce the various doctrines to the vanishing point; those alone survive which do not contain in themselves any elements contradictory to parallelism. The crucial point comes when the idealistic-monistic form is discussed. The author holds an idealistic-spiritualistic doctrine, and is therefore concerned to show that this does not necessitate parallelism, that interaction is not only possible, but preferable. He relies mainly on the unity of consciousness, and the necessity of including activity as subjectively known in our view of the Whole. The arguments against "conservation of energy," "continuity," and naturalistic positions in general are then brought forward. The author is emphatically opposed to any compromises. Between mind and matter the break is absolute; activity without expenditure of energy, the extension downwards to the unconscious or to *quelque chose d'analogique*—in short, compromise of all kind is rejected. Philosophy must here take its stand upon experience, and claim that interaction alone does justice to the facts. The rejection of a preestablished harmony makes it necessary to assert that ultimately we must formulate any given series of events, not as one or as two homogeneous series, either physical (as $a\ b\ c\ldots$) or psychical ($\alpha\ \beta\ \gamma\ldots$), but as a compound series of the form $a\ \beta\ c\ \delta$, &c. Similarly the rejection of any development of mind from lower elements is followed by the conclusion (after Lotze) that it supervenes on a certain development of "Zellengruppe." It follows that so far as interaction is concerned we must assert a dualism; the two systems which interact must be kept distinct; the ultimate unity is not to be found in their nature, but in the fact of their interaction; we have not to piece together the world, but to accept its living unity.

Clearly such a theory claims attention more for the consequences to which it looks than for the advantages it attains. So far we must regard the Weltanschauung of the closing section as much more than a "dessert." Here there appears an "All-Geist," and with it new possibilities; unfortunately the binder omitted some pages here, and criticism must therefore turn upon him rather than upon the author. As an exposition of how experience may be treated in the interests of a Weltanschauung, we have here an admirable discussion. Much of it is common property among writers on the philosophy of psychology. But refutation has before now proved a two-edged sword, and on the crucial points, the subjects of activity and of development, the author seems to glide from proof to assertion. The idealistic treatment of the two factors said to interact presumably forms the ground of a final unity; the question "how" is more easily solved *ambulando* than *cogitando*. It seems to require more than the author's theory of Thing-monads and Soul-monads—more even than the binder can have omitted. G. S. B.

THE NEW ENCYCLOPÆDIA.

Encyclopaedia Britannica. Vol. xxxi. New volumes. Vol. vii. Mos—Pre. (London: A. and C. Black; and the *Times* Office, 1902.)

THE prominence given to scientific subjects in the seventh of the new volumes of what has long been regarded as our national encyclopædia serves in a measure to indicate how large a part the work of men of science has taken in the increase of knowledge during the last quarter of a century. Among articles of prominent importance in this volume, so far as the student of science is concerned, are those dealing with palæobotany, pathology, and physiology, though there are many other articles of a less exhaustive kind dealing with problems of great scientific interest. Technological questions receive due attention, and are represented, among others, by essays on navies, ordnance, paper manufacture, petroleum, photography, and elec-

tric, hydraulic, and pneumatic power transmission. Students of geography and history are provided with an abundance of material, including the latest statistics referring to the chief countries of the world the names of which fall alphabetically between Natal and Portugal, besides an elaborate account of the polar regions, and an able review of the present state of our knowledge of oceanography. Mathematicians will find the article on "Number" both interesting and original, and readers who prefer biographical studies will meet with appreciative estimates of the lives of such celebrities as Owen, Paget, and Pasteur, to name only three.

But no mere mention of a few of the contents can serve more than to give a vague idea of the variety of valuable material brought together in this volume, and the space available makes it possible to refer only to a few of the chief contributions.

The prefatory essay of this volume—and it must be remembered that these essays are a distinguishing characteristic of this new edition—is by Mr. Frederick Greenwood, and deals with the influence of commerce on international conflict. In this scholarly presentation of an important problem, Mr. Greenwood shows how the growth of commerce has given rise in recent times to dreams of the extinction of war. He goes on to explain, however, how war became later to be regarded as a trade weapon and an instrument for the provision of new markets; and as the discoveries of men of science have placed resources for the destruction of men at the disposal of the armies of the world so terrible in their efficiency that, to ensure any chance of success in a war between great Powers, each of them must have armies so large and so expensively equipped as to lead to a growing likelihood of war becoming so dreadful and so costly that it would not be endured. Yet notwithstanding the horror and brevity of modern battles, humanity still seems able to bear the excess, and militarism flourishes.

Of another factor influencing the industrial competition of the nations Mr. Greenwood takes no notice, and that is the increased attention being paid by the leading nations to the higher education of their manufacturers and merchants. The combined efforts of armies and nations are not enough to secure commercial supremacy. A nation must, in addition, provide a sufficient number of institutions of higher education to secure opportunities for its citizens to become conversant with modern scientific knowledge, able to apply the principles of science to modern industrial problems, and to extend the bounds of science into the unknown. The volume itself does not, we find, ignore the importance of higher technical education, for in addition to articles with a less direct bearing on the subject, an essay on polytechnics by Sir Joshua Fitch is included. The subject does not appear to have been allotted the amount of space its importance merited, and the consequence is that metropolitan polytechnics are alone described. It is a pity that the opportunity could not have been taken to familiarise British readers with the complete and lavish provision of institutions abroad corresponding to these polytechnics. The comparison to which such an article must have given rise would have shown England's lamentable deficiency and the low position she must be assigned when the sacrifices made by the leading peoples for the establishment of institutions of the higher learning are passed in review.

BIO-CHEMISTRY.

The Chemical Changes and Products Resulting from Fermentations. By R. H. Aders Plimmer. Pp. vi+184. (London: Longmans and Co., 1903.) Price 6*s.* net.

THE number of chemists who are interested in biological problems is now gradually on the increase, whilst, on the other hand, the biologist realises the importance of a further investigation of the chemical changes concomitant with life. In these circumstances, the book of Dr. Aders Plimmer cannot fail to be particularly welcome, and the perusal of this admirable *résumé* of the work in the borderland between biology and chemistry will indicate to the reader how much has been done and how much still remains to be done in this most difficult field of research.

Under his treatment of polysaccharides the author gives a succinct account of the chemistry of starch, and then proceeds to discuss the changes undergone by monosaccharides and glucosides. In this connection due prominence is given to the recent important observations of Croft Hill, Emmerling and E. Fischer and E. F. Armstrong on reversible ferment action. In the chapter on changes in esters reference is made to the work on lipase, where Kastle concludes that ferments do not act on substances which can be electrolytically dissociated. It should be noted, however, that Slimmer has subsequently pointed out that this view cannot be maintained, since glucovanillic acid and other electrolytes are attacked by emulsin. Other chapters include changes in urea and uric acid, blood, albumins, and changes occurring as a result of oxidation and reduction. Nitrification and denitrification are also considered, and the volume is completed by an account of the changes occurring as the result of putrefaction.

It is pointed out in connection with lactic acid production by microorganisms that the usual product is the inactive acid, but that one of the pure optically active forms may sometimes be obtained. In this latter case the author is apparently of the view that the inactive acid is first of all formed and then converted into the one active form by the selective action of the organism. Experimental evidence, however, seems to show that, if the action were of this nature, the resulting product would not be the pure active acid but rather a mixture of inactive and active acids. Frankland's resolution of *i*-glyceric acid, where the one active constituent is attacked by *Bacillus ethaceticus* and the other apparently remains untouched, is altogether exceptional. In those cases, however, where the lactic acid obtained is optically active, but is mixed with some of the inactive form (as in Harden's experiments on the action of *Bacillus coli communis* on *d*-glucose, &c.), the possibility of the intermediate

formation and subsequent partial resolution of inactive acid may be maintained. In the discussion of Harden's results (p. 69), it is not clear why the lactic acid formed should be optically active at all; from the description given it appears that the asymmetry of the molecule must disappear altogether.

Dr. Plimmer points out that many of the changes caused by living organisms may possibly be due to enzyme action. In addition to his experiments with zymase, Buchner has lately submitted further experimental evidence in favour of this conception, since, conjointly with Meisenheimer, he has proved that from *Bacillus acidificans longissimus* an enzyme may be prepared which converts cane sugar into lactic acid. The same investigators have also shown that the conversion of ethyl alcohol into acetic acid may be accomplished by an enzyme which they obtained from vinegar bacteria.

Buchner's work on zymase surely merits more than the few lines which the author devotes to it, especially since space is found for an account of many discoveries which are of much less fundamental importance. Reference might also have been made to Bredig's experiments on inorganic ferments. Further, one cannot help regretting that a brief account of Emil Fischer's work on the decomposition products of albuminoids is not incorporated in the volume. Those are, however, minor objections. British workers in different sciences will appreciate Dr. Plimmer's account of biochemistry. A. McK.

OUR BOOK SHELF.

Metallurgical Laboratory Notes. By Henry M. Howe, Professor of Metallurgy in Columbia University. Pp. xiv+140. (Boston: The Boston Testing Laboratories, 1902.)

THE time has passed when practical teaching in metallurgy was a synonym for little more than a course of exercises in assaying. No one recognised this sooner and more fully than Prof. Howe, and his students now devote much of their time in the laboratory to carrying out experiments illustrating the principles which underlie the various processes of the treatment of ores and metals in works. This little volume contains a description of ninety-one such experiments of both educational and instructive value, and constitutes the first attempt to embody the new methods in book form. The author expresses in the preface his feeling that the series of experiments now published is incomplete and shows a lack of balance, and probably many metallurgists will find themselves constrained to agree with him. Those teachers who are convinced that ore treatment is still by far the most important branch of the subject may object to a system in which the majority of the experiments are directed to the study of the treatment and properties of metals. Even the methods will not command universal approval in this country, where students are encouraged to learn to overcome the difficulties occasioned by the use of indifferent implements on the grounds that they will be better fitted by such training to deal with the more serious difficulties unavoidably encountered in the industries. The smoothing away of obstacles, and the reduction to a minimum of the practice in manipulation, have been characterised as "spoonmeat methods." It must be admitted, however, that these views are likely to be held most firmly by the professors who are least adequately supplied with laboratory equipment. Prof. Howe considers that in proportion as less time is devoted to details of manipulation, more leisure is available to the student for "the unwelcome task of thinking," than which nothing could be more important. Perhaps it might be argued that practice in manipulation would make the best laboratory workers, and that practice in thinking would assist in turning out the best general managers. The book is extremely welcome, and breaks ground that must soon be assiduously cultivated. It will be carefully studied by all who have the improvement in the training of metallurgists at heart. T. K. R.

Nature Studies in Australia. By W. Gillies and R. Hall. Pp. v+299. (Melbourne and London: Whitcombe and Tombs, Ltd., n.d.) Price 2s.

THE recognition of the importance of "nature-study," if we are to know anything really worth knowing about animals and plants, in Australia is a satisfactory sign of the times, and an indication that throughout the world the old-fashioned ways of teaching are to be abolished, and also that the days of mere section-cutting and skin-describing are numbered. The greater part of the present little volume is devoted to birds (mammals being left out), of the life-histories of which Mr. R. Hall has for many years been an enthusiastic student, and we must congratulate both authors on the mass of interesting information they have concentrated into such a small space with regard to a number of characteristic Australian species. The majority of the numerous illustrations are the results of the authors' own cameras, and, although necessarily on a small scale, they are, for the most part, excellent examples of bird-photography. One great advantage possessed by the authors is that their subject has a freshness which cannot be claimed for descriptions of British bird-life, and this gives a charm to their work which stay-at-home writers must find it difficult to equal. We must confess, however, to a feeling of dissatisfaction at the use of names like "lunulated honey-eaters" for certain of the species, which are certainly not examples of "nature-teaching," and we are by no means sure that we quite like the "pupil and teacher" style on which the work is planned—it savours a little too much of "Sandford and Merton."

One fact appears of more than usual interest. It is commonly stated in ornithological works that every species of migratory bird breeds in the most northern portion of its range. According, however, to the authors, at least one Australian bird—the double-banded or sand dotterel—goes south to breed, travelling to the south of New Zealand, "that is to say, as far towards Antarctica as it can now get."

Space, we regret to say, prevents our going deeper into the contents of the work before us, the latter portion of which is devoted to the lower vertebrates and invertebrates. We can, however, safely recommend it to the best attention of teachers of nature-study, if only for the fact that a book written on the spot is worth a dozen compilations made elsewhere. The price renders it within the reach of all. R. L.

Considerazioni agrarie sul Piano di Capitanata. By Dr. Nestore Petrilli. Pp. 87. (Naples, 1902.)

THIS work consists of a monograph upon the agricultural conditions which prevail in the great plain of the Capitanata, constituting the northern part of Apulia. Such monographs, which are regularly produced upon the Continent, and provide great assist-

ance to the statesman wishing to get a sound idea of the state of an industry subject to such local variations as agriculture, seem to have dropped out of favour in this country; to parallel them we must go back fifty years to the prize reports on the farming of the various counties which used to be a feature of the earlier numbers of the *Journal* of the Royal Agricultural Society.

The Tavoliere di Capitanata is a dry flat plain with an annual rainfall of only eighteen inches, and a mean temperature of more than 60° F.; the prevailing calcareous subsoil results in there being but little surface water, while the few rivers descending from the Apennines are torrential in their nature, and in consequence have formed a considerable area of marsh. The agriculture of the district is of a primitive character, much of it is pastoral, this being one of the sheep-producing districts of Italy; the cultivated land is farmed on a kind of four-course rotation of hard wheat (macaroni wheat), wheat, oats and fallow, and on the poorer land an even simpler rotation of wheat or oats and fallow alternately is practised. A certain acreage is also occupied by vines and olives.

The author, after a preliminary discussion of the meteorological conditions, geology, &c., of the district, proceeds to describe the system of management which prevails, and sets out in detail the cost of the various operations, rates of wages, and gross returns as regards sheep, wheat and vines. As a means of improving the condition of agriculture he lays stress on the introduction of forage crops, such as temporary pastures, sainfoin and lucerne, instead of the present primitive and exhausting alternation of cereals and fallow.

The Stellar Heavens. By Ellard Gore. Pp. xxxii + 128. (London: Chatto and Windus, 1903.) Price 2s. net.

THE author has brought together in a small compass a list of the more prominent objects in the heavens for the use of possessors of small telescopes. The list is accompanied also by brief historical and introductory information applicable to each class of object treated. There are five chapters in all, and these are devoted to the following subjects:—Stars, double, multiple and binary stars, variable stars, star-clusters and nebulæ, and the stellar universe. In the first of these a brief account, among other topics, is given of the classifications of stellar spectra, but unfortunately the reader is not told that Vogel's classification is based on the assumption that all stars are decreasing in temperature, while a natural and more recent classification, dividing the stars into groups in which they are increasing or decreasing their temperature, is altogether omitted.

The paragraph devoted to the explanation of temporary or new stars is needlessly brief considering the number of views expressed on this important subject. On the other hand, an excellent account is given of the methods of observing the brighter variable stars which are in the reach of amateurs, and it is hoped that this interesting branch of astronomy, one specially suitable for those who have only opera glasses at their service, will be taken up more generally.

The volume will, however, be a very useful help for directing the observer's attention to the various more conspicuous objects in the sky, and although it does not pretend to take the place of that well-known friend of amateurs, namely, Webb's "Celestial Objects for Common Telescopes," it will prove a serviceable guide. The only erratum found was the misspelling of the name of Klinkerfues on p. 23, although the name is indexed correctly.

Departmental Notes on Insects that Affect Forestry. By E. P Stebbing, F.L.S., F.E.S., Forest Entomologist under the Government of India. No. 2. Pp. vii+151–334; plates vii–xix. (Calcutta, 1903.)

THE importance of economic entomology is now fully recognised by the Indian Government, and the publication before us is devoted chiefly to Scolytidæ and other beetles injurious to the bark and leaves of trees, and to their parasites; a few moths and scale-insects are also noticed. Each species occupies several pages, and is fully dealt with under various headings, the most important being description, life-history, relations to the forest, points in the life-history requiring further observation (an extremely important matter), protection and remedies, localities, parasites, fungi, &c. Several species are referred to under their generic names only, but this will not render their identification a matter of any great difficulty. The illustrations are fairly good, and many of them are devoted to galleries of Scolytidæ and to different portions of trees attacked by insects. The illustrations of the Coccid, *Monophlebus Stebbingi*, Green, on plate 14 are very interesting. We are sorry that Mr. Stebbing has overlooked the necessity for adding the author's name to every described species mentioned; it is done in some cases, but is frequently omitted, and many of the species described have "M.S." appended to their names. We presume that these are names published for the first time by Mr. Stebbing himself, in which case he should either have added his own name or else "n. sp."

We are glad to notice the increase of well-illustrated publications on economic entomology, for their value is considerable, both from a practical and from a scientific point of view.

Analytical Chemistry. By F. P. Treadwell, Ph.D. Translated from the second German Edition by W. T. Hall, S.B. Pp. xi+466. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 3 dollars.

THE text-book is compiled from lectures delivered by the author at the Polytechnic Institute at Zurich. The matter is, as one might expect, very largely explanatory of the various reactions, that is to say, it is a book to be studied rather outside than in the laboratory. From this point of view it doubtless serves a useful purpose, for every reaction is clearly described and illustrated by an appropriate equation.

One may doubt sometimes the expediency of simplifying all analytical operations on paper in this way, but, provided practical experience is added as a corrective, the value of an equation as a general guide to a reaction can do no harm.

The book is written in a thoroughly scientific spirit —not a common characteristic of books on this subject —and the author is conversant with the modern theory of analytical chemistry, to which reference is frequently made.

Seeing that prominence is given to minerals in which the different elements occur, one misses the refinements of blowpipe analysis which Plattner and Richter did so much to develop. Possibly this might have made the volume too bulky. As it is, the information seems accurate and complete. There are plenty of tables of separation, and there is a section at the end devoted to the rarer elements. The book is printed on good paper in clear type, and is bound in a substantial cover. Altogether the external appearance, for a work on qualitative analysis, produces a very favourable impression. The translator has done his work well. Whether this justifies the prominence given to his name on the back can scarcely be decided by the reviewer.

J. B. C.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Coleridge's Theory of Life.

THE old subject of the nature of the vital force or vitality having lately been under discussion, allow me to remind some of your readers that Coleridge did not hesitate to enforce his opinion that it came into the domain of the scientific inquirer, and appertained to the other forces in nature. I cannot express an opinion on his theories of the nature of life, but his holding them in any tangible form has had great weight with some persons, in consequence of his being an orthodox Christian, belonging to what is called the religious world, yet he considered that the nature of life was open to investigation like any other natural phenomenon.

I may be allowed to quote a few passages for the information of those who are not familiar with his essay on the "Theory of Life." Coleridge's idea was that physical life is a process or mode of operation, as we recognise under such names as magnetism chemical affinity, for these, he says, by their own properties affect all the results observed in life. "Life supposes a universal principle in nature with a limiting power in every particular animal, constantly acting to individualize and as it were *figure* the former. Thus then life is not a thing—a subsistent hypostasis—but an act and process." "To account for Life is one thing, to explain Life another. To a reflecting mind indeed, the very fact that the powers peculiar to life in living animals *include* cohesion, elasticity, &c. (or, in the words of a late publication) 'that living matter exhibits these physical properties' would demonstrate that in the truth of things, they are homogeneous and that both the classes are but degrees and different dignities of one and the same tendency. Unless therefore a thing can exhibit properties which do not belong to it, the very admission that living matter exhibits *physical* properties, includes the further admission that those physical or dead properties are themselves vital in essence, really *distinct* but in appearance only *different*; or in absolute contrast with each other." "If I were asked for what purpose we should generalise the idea of Life thus broadly, I should not hesitate to reply that were there no other use there would be some advantage in merely destroying an arbitrary assumption in natural philosophy and in reminding the physiologists that they could not hear the life of metals asserted with a more contemptuous surprise than they themselves incur from the vulgar when they speak of the life in mould or mucor. But this is not the case. This wider view fills up the arbitrary chasm between physics and physiology and justifies us in using the former as means of insight into the latter."

The author then proceeds to discuss his argument through the lowest creatures in animal life until he reaches man.

"The arborescent forms on a frosty morning to be seen on a window or pavement must have *some* relation to the more perfect forms developed in the vegetable world." He then alludes to the different classes of animals, and says, "as the individuals run into each other so do the different genera. They likewise pass into each other so indistinguishably that the whole order forms a very network. Man forms the apex of the living pyramid. He has the whole world in counterpoint to him but he contains an entire world within himself."

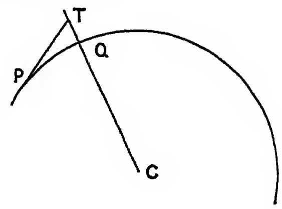
It is clear, therefore, that Coleridge (and others may do the same), whilst holding strictly to the belief in a spiritual existence, yet regarded vitality from quite a different point of view, resulting, indeed, from a combination of forces as we see in other phenomena of nature. SAMUEL WILKS.

Psychophysical Interaction.

SIR OLIVER LODGE says (p. 53) that he would "interfere with the course of nature," regarded as a mechanically determinate problem, even by lifting a log. Why so? The course of nature is exactly what happens, is it not? It is the business of scientific men to find out the course of nature, and the various connections which give it coherence and consistency and determinancy. This has been largely done, even in vital processes: and in the obscurer regions of psychics it seems probable that the course would be determinate if we knew all the circumstances. In any case we have nothing else but the course of nature to go by, in the determination of its laws, and that psychic phenomena are natural phenomena is, it seems to me, the only rational view to take. OLIVER HEAVISIDE.

May 21.

MAY I contribute a pictorial illustration to the controversy raised by Sir Oliver Lodge?



P Q, part of a circular path described by a body of mass m round a fixed centre C, under the influence of a constant centripetal force of magnitude F. Whether this is supplied by a string with a tension F or by an attraction which will be constant if the path is circular does not seem to matter in the least.

Now let P T be the tangential distance which would be traversed in a time t if the centripetal force were absent.

When that force is introduced, P will come to Q instead of to T, and the work done by the force consists of pulling the mass from T to Q in the time t. The energy required to do this is $F \times TQ$, and the same amount is required and absorbed in each successive interval of t. This result is not affected by calling F a guiding force, which it is. If instead of a body describing a circle we had dealt with a body at rest in the position T, the energy required to bring it to Q would be exactly the same.

If Newton had had to express himself (modern fashion) in terms of energy, can we imagine him dealing with the problem except in some such way as my drawing indicates?

Athenæum. G. W. HEMMING.

ATMOSPHERIC ELECTRICITY.

UNTIL within the last two or three years, the advances made in our knowledge of atmospheric electricity were mainly due to the investigation of the electric field of the earth. An interesting summary of the facts brought to light by such investigations will be found in a paper by Exner in "Terrestrial Magnetism and Atmospheric Electricity" (vols. v., p. 167, and vi., p. 1).

Except at or near places where rain (or other form of precipitate) is falling, there is in the free atmosphere an electric field tending to drive positive electricity downwards; the earth's surface is thus in fine weather regions negatively charged. The strength of the electric field and the magnitude of the charge per square centimetre on level ground at a distance from trees or buildings may be found by observing the potential at a measured height. According to Exner, the normal (fine weather) potential gradient in European latitudes varies from about 80 volts per metre in summer to 400 or 500 volts per metre in winter.

It has now been established by means of balloon observations that the intensity of the electric field in fine weather begins to diminish when a comparatively small altitude is reached, and at a height of 5000 metres has only a small fraction of the intensity at the earth's surface. This shows that the lower layers of the atmosphere possess a positive electrification very nearly equivalent to the negative charge on the ground.

For the study of the variations of the electric field at a given place a large mass of material is furnished by the electrograph curves obtained at various observatories. There is a well-marked annual variation in the intensity of the electric field; the maximum occurs in winter and the minimum in summer, the midwinter values being five or six times as high as those of midsummer. The daily variation is less regular, and its character depends on the place of observation and on the season of the year. Three types are recognisable according to Exner. Most commonly there are maxima about 8 a.m. and 8 p.m., with night and noon minima between them. There may, secondly, as on the Eiffel Tower[1] and in winter at many low level stations also, be a minimum in the early morning hours, and a flattened maximum over the day hours. Finally, as in Ceylon and on the Indian Ocean, there may be no daily variation.

A great advance was made in 1899 by Elster and Geitel. They proved, in agreement with previous experiments of Linss, that an electrified body exposed in the open air loses its charge comparatively rapidly by leakage through the air; the leakage is more rapid the clearer and more free from dust the air may be. They showed that the phenomena were entirely in agreement with the supposition that the atmosphere contains positively and negatively charged ions free to move under the action of the electric field. An interesting account of the application of our knowledge of gaseous ions to the explanation of many of the phenomena of atmospheric electricity has been given by Geitel.[2]

Charged conductors exposed in the open air are found to lose 1 or 2 per cent. of their charge or more per minute; the leakage from negatively charged bodies is often somewhat greater than that from positively charged bodies; this difference is especially great on mountain peaks, where a negative charge may be neutralised many times as fast as a positive one, indicating an excess of positive ions. Ebert[3] found in balloon ascents an increased rate of neutralisation in the upper atmosphere as on mountain peaks, but without any marked difference between positive and negative leaks. Many observers, especially in Germany, have lately been carrying out measurements of this "Elektricitätszerstreuung."

There have, however, been very few absolute measurements from which the number of ions present per c.c. in the open air could be determined. Measurements of this kind have been made by Ebert and by Rutherford and Allen. The latter observers found (*Phil. Mag.*, December, 1902) for the number of ions per c.c. of air drawn in from outside their laboratory values which on certain occasions were as low as ·30 per c.c., the charge carried by each ion being about 3×10^{-0} electrostatic units, according to recent determinations by J. J. Thomson (*Phil. Mag.*, March) and by H. A. Wilson (*Phil. Mag.*, April). Rutherford and Allen also showed that the velocity of the ions of the free atmosphere under a given strength of field was approximately the same as that of the ions produced by Röntgen and Becquerel rays, being about 1.4 cm. per second for a potential gradient of a volt per cm.; we are probably therefore justified in assuming an identity in other properties also. With the above values for the number of ions and their velocity, the charge on the ground should be neutralised at the rate of about a half per cent. per minute.

In connection with the question of the origin of the ions in the atmosphere, some remarkable phenomena have to be considered. Even in dust-free air in a closed vessel in the dark there is a continuous production of ions, generally at rates not differing greatly from 40 per c.c. per second, if we interpret the measurements in the light of the most recent determinations of the ionic charge. It has, however, been shown by McLennan and Burton,[1] and by Strutt (NATURE, February 19), that the greater part of the effect is due to the walls of the vessel, that ordinary substances in varying degrees resemble radium in being radio-active and producing radio-active emanations, the effects, however, being of incomparably smaller intensity. The two first-named experimenters also found that a part of the ionisation is due to an extremely penetrating radiation from sources outside the vessel. Rutherford and Cooke (NATURE, April 2) have obtained a similar result. Elster and Geitel found that negatively charged bodies exposed in the open air become temporarily radio-active, just as they do when exposed to the emanations from radium or thorium. Vessels in which freshly fallen rain or snow have been evaporated to dryness show a similar temporary radio-activity.[2] The atmosphere apparently contains an emanation like that from radium. Air pumped out of the ground shows these effects to an abnormally marked degree, as Elster and Geitel have proved. The surface of the ground, and to a still greater extent the exposed portions of trees, must, it will be observed, under normal fine weather conditions become radio-active in virtue of their negative charge, and produce, therefore, an abnormal amount of ionisation in the air near them.

It is probable, in the light of Lenard's experiments, that sunlight ionises the air which it traverses, especially in the upper atmosphere, while it is still strong in ultra-violet rays.

The conductivity of the air increases in a sense the difficulty of the problem of the origin of the earth's electric field. For it would seem that the electric field in fine weather regions should rapidly diminish, and in a few hours disappear; there must be some process by which the electric field is continually being regenerated. Leaving aside, however, the consideration of the origin of the electric field, we may attempt to explain its variations as due to the variations in the conditions determining its rate of destruction. Whatever increases the conductivity of the air will diminish the electric field, and *vice versâ*. Examples of the application of this principle will be found in the paper by Geitel already mentioned. To take only one, the increase in the electric field accompanying fogs (a phenomenon well shown in the Kew electrograph curves) may be explained as due to the entangling of the ions by the fog particles; the leakage of electricity under such conditions has been found by Elster and Geitel to be very slight.

In regions enjoying fine weather, if we assume the existence of a flow of electricity in the direction of the electric field, there will be a downward earth-air current; there must then be a compensating current accompanying precipitation, negative electricity being brought down in the rain, and the positive charge being left behind in the atmosphere and carried by upper air currents to other regions. There is, as we shall see later, reason to believe that an excess of negative electricity is brought down to the earth's surface by rain. It is, however, doubtful whether we can explain in this way the existence of the normal electric field at a distance from regions where rain is falling; for the positively charged upper air currents would continually be losing their charges, and we should expect a rapid falling off in the intensity of the field

with increasing distance from the region of precipitation.

We may, on the other hand, suppose that there are everywhere other influences opposing or neutralising the ion of electricity in the direction of the electric field; so that no earth-air current results. Geitel has offered an explanation of the maintenance of the electric field in fine weather based on a difference between positive and negative ions which was discovered by Zeleny. Negative ions are more mobile than positive, they travel with greater velocity in an electric field and diffuse more rapidly. In consequence a body exposed to a current of ionised air becomes negatively charged; Geitel suggests that the surface of the earth may acquire its negative charge in a similar way. The difference in the velocities of diffusion of the positive and negative ions could not, however, maintain an electric field except close to the ground, unless air currents were present to carry up the positively charged layers produced at the earth's surface.

It is quite conceivable that we may be driven to seek an extra-terrestrial source for the negative charge of the earth's surface. The study of the aurora borealis has led several observers to the conclusion that the sun emits kathode rays, which are deflected by the earth's magnetic field, and travel in helical paths round the magnetic lines of force towards the poles. It is conceivable that very penetrating rays of this type (*i.e.* negatively charged electrons) may traverse our atmosphere unabsorbed, and be stopped in the solid mass of the earth, giving to it their negative charge.

We have now to consider the electrical phenomena accompanying precipitation. As already indicated, precipitation is nearly always associated with the occurrence of negative values of the potential gradient. Heavy showers of rain, snow, or hail are accompanied by rapid alternations of high positive and high negative values of the electric field, generally too high to be measured by electrograph apparatus arranged to suit fine weather conditions. In extreme cases we have thunderstorms. There are cases of rain not associated with negative potential gradients; these are practically all cases of slight rain, generally mere wet mist or drizzle. Clouds from which rain is not falling rarely show marked electrical effects. To find by direct observation whether rain is charged with electricity is a matter of extreme difficulty. Elster and Geitel's observations appear to show that raindrops are charged, and that the sign of the charge frequently changes during a shower, negative values, however, on the whole prevailing.

The following are possible factors in the production of the intense electrical fields which accompany heavy showers.

A less degree of supersaturation is required to make water condense on the negative than on the positive ions (C. T. R. Wilson, *Phil. Trans.*, vol. cxciii. p. 289). Thus, if condensation takes place from the supersaturated condition, the drops formed are likely to be negatively charged; that the drops, formed in ionised air by expansions slightly exceeding that required to cause condensation on negative ions, are actually negatively charged has been proved by H. A. Wilson (*Phil. Mag.*, April). Since, however, each drop will only carry the very small ionic charge, the electrical effect will be small if only a few large drops are formed; if a large number of negative ions serve as nuclei of condensation, the drops will be small, and will only fall slowly relatively to the air; the resulting electric field cannot exceed that which drives positive ions downwards as fast as the negatively charged drops fall under the action of gravity. The field initially produced may, however, be strong enough to induce coalescence of drops which come in contact (Lord Rayleigh, Roy. Soc. *Proc.* xxviii. p. 406), and we may thus get drops carrying many times the charge of one ion, and large enough to fall rapidly. Strong fields may then result.

Again, we should expect (NATURE, vol. lxii. p. 149) drops falling through ionised air to become negatively charged as a result of the difference in the mobility of the positive and negative ions. This effect has, in fact, been experimentally demonstrated by Schmauss (*Ann. d. Physik*, vol. ix. p. 224).

If collisions resulting in splashing occur between raindrops (and they are likely to be frequent in the uprush of air in thunderstorms), positively charged rain may be formed. For, as Lenard has shown, when splashing of pure water occurs, as, for example, in waterfalls, the air in the neighbourhood acquires a negative, the water a positive, charge.

Apart from the Lenard effect, the splashing resulting from the collision of drops in an electric field may have large effects, either in intensifying or diminishing the electric field already existing, the action being like that of an electrostatic influence machine. The result would be to increase the intensity of the field if the splashes were thrown out from the lower portion of the combined drop. If, for example, the field were such as to produce positive electrification on the lower surface of a neutral drop, a droplet leaving the lower surface would be positively charged, and being carried upwards by the air relatively to the large drop, would add to the intensity of the primary field.

C. T. R. WILSON.

RAINFALL AND RIVER FLOW IN THE THAMES BASIN.[1]

THE Water Committee of the London County Council in December, 1902, called upon their chief engineer for a report on the diminution of the volume of water in the Thames and Lea, and his report was submitted to the Council in February. It deals briefly with the geology of the Thames and Lea basins so far as geology affects waterworks engineering, and in greater detail with the rainfall and the flow of the streams. The general result of the inquiry is thus stated:—

"For the past twenty years there has been a decline over the Thames watershed of an annual average of nearly 2½ inches below the mean rainfall of 28.50 inches, as computed by the late Mr. Symons for the forty years 1850–89; and I may add that this diminution has become more accentuated during the last five years. This decline is reflected in the diminished flow of the river as gauged at Teddington Weir, the natural flow having fallen to an average of 1110½ million gallons daily at the intakes for the 20 years compared with 1350 million gallons over the 1850–89 period, showing a loss to the river of 239½ million gallons per day. As the diminished rainfall of 2½ inches equals 105 million gallons per day (after making an allowance for evaporation, &c., of roughly 70 per cent.), and the above diminished flow of 239½ million gallons shows a difference from this of 134½ million gallons daily, it would appear as though the condition of the river was becoming more acute, inasmuch as more rainfall would be required year by year to produce the long-period average rate of flow; in fact, what this means is that the percentage of total rainfall which reaches the river is diminishing as well as the total rainfall itself. Of course, against these facts we have the possibility of a long series of wet years, which

[1] London County Council. Shrinkage of the Thames and Lea Report by Maurice Fitzmaurice, C.M.G., Chief Engineer. Pp. 18; plates. (London: P. S. King and Co., 1903.)

may bring back the state of affairs which existed on the average during the long period mentioned."

The fact that we are at present in a period of relatively low rainfall is, of course, well known, and as regards the Thames Basin, the following table is quoted, giving the average annual fall deduced from twenty-four well-distributed stations:—

Year	Inches	Year	Inches	Year	Inches	Year	Inches
1883 ...	28·41	1888 ...	28·45	1893 ...	22·08	1898 ...	22·07
1884 ...	22·90	1889 ...	25·65	1894 ...	32·33	1899 ...	24·78
1885 ...	29·15	1890 ...	22·81	1895 ...	26·32	1900 ...	27·88
1886 ...	31·07	1891 ...	33·31	1896 ...	25·82	1901 ...	23·47
1887 ...	21·32	1892 ...	23·02	1897 ...	27·79	1902 ...	21·91

The report points out that the mean rainfall for the ten years 1883–92 was 26.60, and for the ten years 1893–1902 it was 25.44, or more than an inch less. But it is not clearly pointed out that the means of the four consecutive periods of five years give the respective values 26.57 in., 26.65 in., 26.87 in., and 24.02 in., in other words, that on the whole the rainfall was increasing slightly for fifteen years, and fell sharply in the last five. Nor is attention called to the fact that the average rainfall of 28.50 inches for the Thames Basin was arrived at by Mr. Symons in 1893 from the consideration of a much larger number of stations than the twenty-four on which the subsequent values are based, for the ten years 1880–89, which period Mr. Symons showed probably gave the same mean value as the long period 1850–89. It is probable that the latter figures represent the average rainfall of the basin as accurately as so small a number of stations can, and they are at least comparable *inter se*, but it is by no means so sure that they can fairly be compared with the earlier mean value obtained by the consideration of a much larger number of stations. In fact, we are not inclined to look upon the decline in the rainfall as quite so serious as it appears to be from the report, and we are confident that in the course of time, and probably in a comparatively short time, the fall will again reach the average.

The report shows plainly that the diminution in the flow of the Thames (and the same holds good of the Lea) is greater than the diminution of the rainfall. Theoretical considerations suggest that this is what should occur, for the amount of water absorbed by vegetation must be approximately constant, and in a dry year evaporation is usually more active than in a wet one, while, when the water-level in the pervious rocks is lowered, the flow of springs cannot respond to the rainfall with the promptitude usual when the rocks are saturated.

It is a matter of regret that hydrology, as applied to the rivers of the whole British Isles, has not been taken up by any Government department. This report of the County Council shows the interest of the problems involved, and it may be that a more systematic treatment of statistics of rainfall and river-flow would answer the questions which is suggests.

HUGH ROBERT MILL.

ARCTIC GEOLOGY.

As the report on the geological observations made during the recent Polar expedition of the *Fram*, recently read before the Royal Geographical Society by Mr. P. Schel, of which we have received a separate copy, is only a preliminary one, and the geological terms employed require some revision to make them intelligible to an English reader, a brief notice may suffice, though evidently the results will be very valuable. Under Captain Sverdrup's leadership, Ellesmere Land was crossed, part of its southern and its western coast was traced, with the corresponding side of Grinnell Land, and journeys were made round Axel Heiberg and Ringnes Islands. The collections obtained, which were often considerable, show that the region explored, with the newly discovered islands, consists of formations which were known to occur on the two sides of Smith Sound and on the long chain of islands extending on or near the seventy-fifth parallel from North Devon to Prince Patrick Island, viz. a foundation of crystalline Archæan rocks, largely granitoid, followed by sedimentaries the oldest of which are of Cambrian age, the part immediately following the Archæan being occasionally, as might be expected, an arkose. In some places representatives of the Ordovician and Silurian occur, and, as in the other islands, Devonian and Carboniferous, including the representative limestone, are extensively developed. Mesozoic formations are represented, but apparently on no great scale, and large masses of sandstone, with lignites and shales, are identified by their plant fossils as Tertiary (Miocene or perhaps rather earlier), as in Greenland. In parts of Ellesmere Land and Heiberg Island are various eruptive rocks, porphyrites and diabases, cutting the Archæan and the older sedimentaries. Basalts and dolerites occur in Grinnell Land intrusive in Mesozoic strata, and surface lavas and somewhat similar rocks overlie Carboniferous rocks in Heiberg Island. They are older than the Tertiary shale mentioned above. The region has occasionally been much faulted, and locally crushed up against a "horst" of Archæan rock. It has also been affected by earth movements of late date, indicated by raised beaches and marine terraces, which are at various elevations up to nearly 600 feet, and so prove that the land has risen. There are no large masses of inland ice or signs of glaciers having formerly been on a much more extensive scale than at present. This is probably due, at any rate partly, to a rather small precipitation.

J. V. LABORDE (1830–1903).

DR. LABORDE (Jean Baptiste Vincent), who died recently at the age of seventy-two, was born at Buzet (Lot et Garonne), and received a good education at the Lycée of Cahors, after spending some time in a boarding-school at Casteljaloux. To satisfy his natural bent for medical studies he went to Paris, without any resources, and, in order to provide for his livelihood and his studies, he was obliged to give private lessons. However, he managed to be appointed *externe des hopitaux in* 1854, in the same promotion as Lancereaux, now president of the Académie de Médecine. Four years later, he obtained the *internat*, in which capacity he spent four years more in the hospitals of Paris, after which he was graduated doctor médic. for his thesis on "La Paralysie Infantile" (1864). Meanwhile he had obtained the gold medal of the hospitals, the Corvisart prize, and another prize from the Société Médicale des Hopitaux, and, lastly, in the very year in which he got his doctor's degree, the Godard prize, awarded by the Société Anatomique de Paris.

In 1872 Laborde gave up pure medicine to devote himself to scientific works, particularly to physiology, giving to his researches a solid and safe basis, by means of the experimental method. At first only an assistant to Prof. Béclard, he was soon appointed chef des travaux de physiologie at the Faculté de Médecine, and for many years the demonstrations he gave in his laboratory were attended by numerous pupils. It was in the course of this period that he published the

greater part of his works, always seeking in physiology pathological deductions for the use of practitioners.

As regards pure physiology, he studied the acid of the gastric juice, trying to show that it never existed uncombined (1874–77), the rhythmical function of the heart and its development in the embryo (1876), and more especially the function of the central nervous system, and of the bulb in particular (1877–1880). In this way he showed the existence of two bulbar centres, one acting upon breathing (it was the centre of Le Gallois and Flourens), the other upon the cardiac muscle, which clearly explained the two possible causes of death, either a stop of the respiratory movements with persistence of the beating of the heart or *vice versâ*. He showed also the functional association of the eyes in the binocular vision, owing to the narrow connections between their motor nerves. As regards the physiology of the nerves, again, he revealed the existence of the tractus of crossed hemianæsthesy, published a few notes on the excitability of the nervous centres, the reflex movements, the functions of the semicircular canals (1881), and, lastly, a refutation of the theory which made the cerebellum the seat of muscular strength.

Not less numerous are the works that he published upon experimental and comparative pathology.

But his special study was experimental physiology applied to therapeutics and toxicology; he published works on the properties of many substances, such as the narceine (1866), which he considered as the best sedative of the nervous system; the bromides, the soothing influence of which he investigated (1867–1869); the eserine or alkaloid of the Calabar bean (1869); propylamine (1873); aconitine, the advantages of which he showed as a sedative of sensibility (1875); colchicine, sparteine, boldo, salts of strontium, &c.; lastly, in 1877, he published a study on the alkaloids of cinchona, which he named in the following order, according to their poisonous qualities: Cinchonine, cinchonidine, quinidine. In fact, he made a special study of poisons in general, animal as well as mineral, natural as well as artificial.

In concluding this cursory view of Laborde's works, we cannot do better than mention his ingenious method of the rhythmical tractions of the tongue, which was sufficient to make the name of its inventor known throughout all the world. There is no need to expatiate on this most simple and efficient process of setting the respiratory reflex to work. It is known and used everywhere, and it has called back to life numbers of apparently drowned or suffocated people.

In fact, Laborde was not only a savant, but a great philanthropist, and this quality, together with his profound knowledge of toxicology, brought him to the front as one of the best qualified in the controversy raised recently on the question of alcoholism.

For this reason, Laborde, who had been a member of the Académie de Médecine since 1887, was trusted by this learned body with the report on the essences to be forbidden as noxious, which the Government had required from them. In this work he exhausted what strength was left to him. He strenuously defended every one of his arguments against the objections of his colleagues, and at last succeeded in making them adopt every item of his report. But the work proved too much for him, and he died on April 5. He was vice-president of the Society of Biology, director of the Laboratory of Anthropology at the École des Hautes Études since 1893, and professor at the School of Anthropology. He was besides one of the oldest and ablest scientific journalists. He started *La Tribune Médicale*, a periodical open to all young medical men, which he edited to the last.

He was one of the few French savants who did not belong to the Legion of Honour. Of course, the decoration was several times offered to him, but he thought it a distinction which should be exclusively military, and he never allowed his actions to contradict his opinions.

J. Deniker.

NOTES.

A meeting of the council of the International Association of Academies is being held this week at the rooms of the Royal Society, that society being the directing academy of the association for the three years' period ending with 1904. The meeting will be attended by delegates from nearly all the principal learned academies of Europe, and will discuss several matters of importance to international science and philosophy, preparatory to the meeting of the general assembly which is to be held in London next year. Representatives of both sections of the association, the natural science section, and the history and philosophy section, will attend the council. In connection with the meeting of the council there will be on Friday a meeting of a special committee appointed to deal with a proposal for the establishment of an international organisation for the investigation of the anatomy of the brain. The foreign delegates were to be received by the president and fellows of the Royal Society at Burlington House on Wednesday evening as we went to press.

The reply given by Mr. Balfour in the House of Commons on May 26, in answer to a question as to what the Government proposed to do to ensure the safety of the National Antarctic Expedition, was a rebuke which should not be received in silence by the joint Antarctic Committee. Mr. Balfour said:—" The Government are prepared to contribute to the relief of the officers and men on board the *Discovery*, which is now ice-bound in the Antarctic seas. The course taken by the two learned societies responsible for the expedition in respect to the contribution of money and men made by the Government is greatly to be regretted. I have always leaned towards the principle of extending the very limited aid which the British Government have been accustomed to give towards the furtherance of purely scientific research; but such action can only be justified so long as the Government are able to feel absolute confidence that the scientific bodies approaching them have placed before them all the information in their possession as to the estimated cost of their proposed action, and the limits within which they intend to confine it. That confidence has been rudely shaken by the present case." This statement has naturally received much attention, and the Antarctic Committee cannot permit the charges it contains to pass without reply. The two learned societies referred to are the Royal Society and the Royal Geographical Society, and the management of the expedition is in the hands of a joint committee of these bodies. From the beginning, however, the Royal Geographical Society has exerted a preponderant influence in the organisation of the expedition, and the Royal Society has yielded to it against the advice of its own representatives. When vital matters connected with the conduct of the expedition were in dispute in 1901, we on several occasions criticised the methods adopted, and regretted that the Royal Society had not taken a firmer position. Because the council of the Royal Geographical Society would not accept the recommendations of the joint committee, the Royal Society allowed itself to be overruled, though Sir Archibald Geikie, Prof. E. B. Poulton and Mr. J. Y. Buchanan objected to the surrender. The whole story was told in a letter sent by Prof. Poulton to fellows of the Royal Society, and published in Nature of May 23,

1901. This protest was, however, disregarded, with the result that the Society now finds itself held responsible for management which has really been left to the geographers. The *Daily Mail* has published several articles in which the joint committee is severely handled, and the facts disclosed as to the estimated and actual costs of the expedition are, to say the least, such as will not encourage the public to believe in the foresight and business capacity of men of science.

THE condition of the German Antarctic Expedition which, under the command of Dr. von Drygalski, left Germany in August, 1901, is causing great anxiety, and hurried preparations are being made for the dispatch of a relief expedition this summer. It will be remembered, a correspondent of the *Pall Mall* remarks, that a station was erected on Kerguelen Island in January, 1902, which was intended to serve as a place of observation and as a base for the expedition ship *Gauss*, which was to penetrate much farther south. Those who were at the station, however, suffered terribly from the climate, and then were attacked by beri-beri, which appears to be endemic in that part of the world. This malady carried off the greater number of those who were afflicted with it, among them being Dr. Enzensperger, the meteorologist. The *Gauss* sailed south, but as nothing has been heard of her for a long time it is feared that she is lost, and doubts have been expressed that any of her present officers and crew will ever be heard of again. An attempt is, however, to be made to find them. The matter was discussed in the Reichstag a few days ago, and about 25,000*l*. was unanimously voted for a relief expedition. Preparations for departure will not be begun until the middle of next month—the latest time, according to scientific opinion, that the *Gauss* could by any chance make her way out of the vast fields of ice over which the terrible severity of an Antarctic winter is now spreading.

THE fifth International Congress for Applied Chemistry is being held in the Imperial Diet Building at Berlin, under the presidency of Prof. Dr. Otto N. Witt. About 2200 members, accompanied by more than 300 ladies, are attending the Congress, at which the European States and several other States are represented by official delegates. The chief British societies, that is, in addition to the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry, the Society of Public Analysts, the Federated Institute of Brewing, the Royal Societies of London and Edinburgh, the Iron and Steel Institute, the Royal Institution, the British Association and other bodies, nominated delegates for the organising committee. The Congress will deliberate in eleven sections and three subsections. The German Electrochemical Society, which last year adopted the name of German Bunsen Society for Applied Physical Chemistry, will also hold its annual meeting at Berlin during this week, and will take charge of the tenth electrochemical section. This section, however, will meet in the Physical Institute of the University of Berlin. The congress offices, so far at 31 March Str., Charlottenburg, will be removed to the Imperial Diet Building (Reichstags-Gebaüde) on June 2, and a post office has been opened in this building for the convenience of members. There are 350 papers and reports to be read. The great electrical works of Berlin and some other works will be thrown open to members, but no chemical works apparently. The city of Berlin will entertain the Congress, and an excursion to the Havel Lakes has been arranged for Sunday, June 7.

THE proceedings of the International Telegraph Conference, at which nearly fifty different States are represented, commenced last week, and will continue day by day during this month. The proceedings are private. Mr. J. C. Lamb, the principal delegate of Great Britain, has been elected president of the conference, and Messrs. J. Ardron and P. Benton vice-presidents. This is the ninth conference which has been held; at the last the cable companies have been represented as well as the various States. In addition to the business of the conference, dinners and other entertainments have been arranged in connection with it; a dinner was given last week by the Submarine Telegraph Companies at the Hotel Cecil, Sir J. Wolfe-Barry presiding, and nearly 500 guests being present. The president of the Institution of Electrical Engineers entertains the delegates and the Institution at a concert at the Albert Hall on June 11, and the conversazione of the Institution will also be held during the sitting of the conference.

MR. MARCONI is reported to have said on his return to England last week that it will be another six weeks before Transatlantic communication will be resumed. The precise nature of the breakdown has not been published. The American company proposes to extend greatly the system in America by establishing new stations in New York and on the great lakes. It is also stated that the report that Mr. Marconi was suffering from nervous breakdown and would have to take a prolonged rest is unfounded.

THE council of the Institution of Electrical Engineers has received and accepted an invitation from the American Institute of Electrical Engineers to visit the United States in 1904. The McGill University, of Montreal, has invited the two Institutions to hold a joint meeting in their building at this time. The invitations, both from the American Institute and the McGill University, are couched in the most cordial terms, and the council hopes that it may be possible to arrange not only for a visit to the eastern States of America and to the St. Louis Exhibition, but also for the proposed joint meeting in Canada.

THE report of the council of the Institution of Electrical Engineers, adopted at the annual general meeting held on May 28, is a record of real scientific activity and progress. The Institution is exerting the best of influences upon electrical science, and its work and scope are rapidly extending. Mr. Robert Kaye Gray has been elected president in succession to Mr. Swinburne. A new local section has been formed with its centre at Leeds, embracing the whole of Yorkshire with the exception of Middlesbrough and the Cleveland district, which were already included in the area of the Newcastle local section. The council has awarded the following premiums for papers and communications:—the Institution premium, value 25*l*., to Dr. J. A. Fleming, F.R.S., for "Photometry of Electric Lamps"; the Paris Electrical Exhibition premium, value 10*l*., to Mr. M. B. Field, for "A Study of the Phenomenon of Resonance in Electric Circuits by the Aid of Oscillograms"; two extra premiums, value 10*l*. each, one to Messrs. A. D. Constable and E. Fawssett jointly, for "Distribution Losses in Electric Supply Systems"; and the other to Dr. W. M. Thornton, for "Experiments on Synchronous Converters"; an original communication premium, value 10*l*., to Messrs. A. Russell and C. C. Paterson, for "Sparking in Switches." Students' premiums have been awarded to Messrs. J. Griffin, F. J. Hiss, E. Fisher, A. G. Ellis, and T. H. Vigor. Salomons scholarships, value 50*l*. each, have been awarded to Mr. G. B. Dyke, of University College, London, and to Mr. H. W. Kefford, of the Central Technical College. The award of the David Hughes scholarship, value 50*l*., has been made to Mr. W. H. Wilson, of King's College, London.

It has been decided to christen the new society of electro-chemists "The Faraday Society," the object of the Society, as stated in a subtitle, being to promote the study of electro-chemistry, electrometallurgy, chemical physics, metallography, and kindred subjects. It is proposed to start work at once by beginning a half-session on July 1, the first ordinary meeting being fixed for June 30; the papers to be read will be announced in due course. Arrangements have been made to publish the proceedings in the *Electro-chemist and Metallurgist*, which will be issued free to members; the papers will be circulated before being read, a plan which it is hoped will improve the discussion upon them. It is also hoped that it will be possible to supply members with the *Transactions* of the American Electro-chemical Society, either free or at a very small cost. The first president is Mr. J. W. Swan, F.R.S., and the vice-presidents are Prof. Crum Brown, Lord Kelvin, Sir O. Lodge, Dr. Ludwig Mond, Lord Rayleigh, Mr. A. Siemens and Mr. J. Swinburne. A set of rules has been drawn up by the council; these and any other particulars can be obtained from the secretary, Mr. F. S. Spiers, 82 Victoria Street, S.W. We wish the Society all success.

We regret to have to announce that Dr. A. A. Common, of Ealing, died very suddenly on Wednesday morning last.

Sir William Ramsay, K.C.B., F.R.S., has been elected a corresponding member of the Academy of Sciences of Vienna.

The presentation of the Hofmann medals to M. Henri Moissan and Sir William Ramsay is to take place at the Hofmann-Haus, Berlin, to-day, June 4.

The annual conversazione of the Society of Arts will take place at the Royal Botanic Gardens, Regent's Park, on Tuesday, June 30.

It is expected, says *Science*, that the International Electrical Congress will be held at St. Louis, during the week beginning September 12, 1904. It will immediately precede the International Congress of Arts and Sciences.

At the anniversary meeting of the Linnean Society on May 25, Prof. S. H. Vines, F.R.S., was elected president for the ensuing year. The Linnean medal was presented to Dr. M. C. Cooke.

According to a Reuter message from Paris on May 30, a telegram from Fort de France, dated May 28, states that the volcano of Mont Pelée is again showing activity, and that the Council-General of Martinique is urging the evacuation of the whole of the north side of the island.

According to a Press despatch from Washington, dated May 13, the executive committee of the Carnegie Institution reports that the entire sum of 40,000*l.* allotted to grants for original research has been distributed, and that of the 8000*l.* set aside for publications to be made this year, 4000*l.* has been assigned to special publications. No more grants for researches will be made until after the next meeting of the board of trustees, which will be held in December.

A terrific tornado passed over the southern portion of Gainsville, Georgia, at noon on Monday, June 1, destroying several large buildings and killing sixty-four persons. The track of the tornado was about one hundred yards wide, and the damage done was confined to it. The storm came with great suddenness, and within a couple of minutes the two upper stories of a four-story brick-built factory were carried away to distances of hundreds of feet. During the tornado deep darkness prevailed, and the air was hot and oppressive. Five minutes later the sun was shining.

Extraordinary rains in parts of the United States have caused great damage and loss of life by floods in the Indian Territory, Oklahoma, Kansas, Missouri, Nebraska, and Iowa. At North Topeka, Kansas, seven thousand out of the ten thousand inhabitants left the city on May 30 to escape the deluge. One hundred and fifty persons are known to have been drowned. The rescued say that the whole of North Topeka was flooded on Friday faster than the people could get away. On May 30 the level of the Kansas River rose at the rate of three inches an hour. On June 1 the Missouri River was thirty feet above low-water mark at Kansas City, and was rising rapidly.

On Saturday afternoon, May 30, and following night London was visited by two violent thunderstorms. Storms of a destructive character, resulting in loss of life, also occurred over a great part of England, especially in the Thames Valley, and were apparently due to the passage of small cyclonic depressions moving slowly from south-east to north-west. Heavy downpours of rain accompanied or followed both storms, but its intensity varied considerably; about an inch and a half fell during the first storm in one of the southern suburbs of London, while at a distance of a very few miles, where the thunder and lightning appeared to be equally violent, the fall only amounted to a few tenths of an inch. The heat was oppressive; near London on Whit Monday the thermometer in the screen rose to 83°, and the weather was exceptionally brilliant in the south and east of England generally, but dull and cool in the north and west.

The *Times* states that the master of the trawler *City of Lincoln*, which arrived at Kirkwall on June 1 from Iceland, reported that on the night of May 27, off the south-east coast of Iceland, a volcanic eruption was observed a considerable distance to the eastward, probably at Mount Hekla. Dust fell on the deck of the trawler, and the sea was discoloured to a distance of about thirty miles from the island.

A Reuter message from Constantinople on May 26 states that belated reports have been received of the earthquake at Van on April 29, by which the town of Melazgerd was totally destroyed, with its entire population, numbering about 2000 persons. More than 400 houses in neighbouring villages collapsed. A somewhat severe shock of earthquake was felt in Constantinople on the morning of May 26, but no damage was done. Further particulars of the earthquake at Van are contained in a despatch from His Majesty's Consul at Erzerum. The villages of Patnotz, Hadjili, Mollah Ibrahim, Zoussicko and Molla Mustapha, were completely destroyed with the exception of the mosque, school and two houses. Seventeen other villages have been partially destroyed. In Sipoki the villages of Mollah Hassan, Berdav, Mirzeh, Kara Khelil Alia have been completely destroyed, and eight other villages partially destroyed. It would appear that the centre of the seismic disturbance was in the neighbourhood of Mount Sipan, and the area of its greatest violence extended along the valley of the Eastern Euphrates, covering the Kazas of Boulanyk and Melazgerd, and the Patnotz district.

As already announced, the autumn meeting of the Iron and Steel Institute will be held at Barrow-in-Furness on September 1–4, under the presidency of Mr. Andrew Carnegie. The programme will embrace visits to works, docks, and iron ore mines, and excursions will be arranged to the Lake District and to Blackpool. A detailed programme will be issued when the local arrangements are further advanced. This programme will contain a list of the papers that are expected to be read.

THE twenty-first congress of the Sanitary Institute will be held at Bradford on July 6–11. The inaugural address to the congress will be delivered by the president, the Right Hon. the Earl Stamford. Numerous sectional meetings will be held, the sections with their presidents being as follows:—(1) Sanitary science and preventive medicine, Prof. T. Clifford Allbutt, F.R.S.; (2) engineering and architecture, Mr. Maurice Fitzmaurice, C.M.G.; (3) physics, chemistry and biology, Prof. C. Hunter Stewart. On July 8 there will be conferences of those engaged in the various branches of practical sanitary science, and in the evening a conversazione and reception by the Mayor of Bradford. The concluding day will be devoted to excursions.

THE Physical Society has for several years held its meetings at Burlington House, but the fellows have been given notice that a change is contemplated. It is proposed to hold meetings on the second and fourth Fridays of the month alternately in the afternoon and the evening at the Royal College of Science, South Kensington. The council trusts that convenience and equipment available when the Society meets in a physical laboratory will encourage fellows to illustrate their papers by experiments, and thus add to the interest of the meetings. The council has also under consideration the formation of a student class in the Society. This matter will shortly be brought forward at a special general meeting.

MR. R. S. EARP writes from Buckfastleigh, South Devon, to say that on comparing the results of Prof. Thorpe's analysis of the dust of "red rain" (p. 53) with his own, the chief dissimilarity was found in the amount of organic matter. This may be explained by the fact of Prof. Thorpe's analysis being of the sediment only of the rain, whereas Mr. Earp's was of the rain itself, or rather of the solid constituents of the rain. The rain collected did not clear itself even on long standing, the supernatant liquid being emulsion-like in appearance. Mr. Earp concludes "that the greater portion of the organic matter would exist suspended in the fallen rain, and so would not appear in the result of Prof. Thorpe's analysis."

THE scientific balloon ascents on April 2 were participated in by France, Germany, Austria, Russia, and Blue Hill, U.S., and were made by means of manned and registering balloons, and kites. At Trappes the registering balloon burst at 8550 metres; minimum temperature $-47^{\circ}\cdot0$ C. (at starting $0^{\circ}\cdot8$). At Itteville (Paris) the ascent was made in the evening; temperature $-54^{\circ}\cdot0$ at 9560 metres (at starting $8^{\circ}\cdot0$); an altitude of 12,760 metres was reached. At Strassburg a height of 10,000 metres was attained; minimum temperature $-44^{\circ}\cdot4$, at starting (5h. a.m.) $5^{\circ}\cdot7$. At Berlin one of the several balloons dispatched reached 10,400 metres; at 8380 metres the temperature was $-42^{\circ}\cdot0$ (at starting $2^{\circ}\cdot0$), while another, started two hours earlier (4h. 57m. a.m.), recorded $-47^{\circ}\cdot8$ at 8670 metres. At Blue Hill a kite reached 3067 metres, temperature $-6^{\circ}\cdot2$; at the same time the temperature at the observatory was $8^{\circ}\cdot1$ (height 159 metres). Atmospheric pressure was fairly uniform over Europe on the day of the ascents, and the type of weather was generally cyclonic in character.

IN a paper read before the R. Accademia delle Scienze dell' Istituto di Bologna on January 11, Prof. A. Righi describes experiments on the ionisation of air by an electrified point. Some striking results depending on the motion of the ions along the electric lines of force were obtained. A sheet of ebonite backed by a metal plate was fixed in front of a point discharge, and between them was placed a wire gauze screen, which closed an aperture in a metal case surrounding the discharge. A spark from a Leyden jar to the metal plate produced for a short time a powerful electric field traversing the ebonite plate and the air space between it and the gauze. A well-defined image of the wire gauze was then developed upon the ebonite by treating it with a mixture of powdered sulphur and red lead, which made visible the portions of the ebonite to which the ions had imparted a charge. The "electric shadow" of the wire remains free from charge.

A NEW form of stereoscope for X-ray work is described by M. T. Guilloz in a recent number of the *Journal de Physique*. A single X-ray tube is used, being so mounted that it can be rapidly oscillated between two positions. A cam rotating at a speed of about 300 revolutions per minute is used to oscillate the tube; this cam is cut so that the time taken in moving from one position of rest to the other is about 1/10th of the time of rotation. Two radiographic images of the object under examination are thus formed on the screen which are displaced by an amount varying as the amplitude of oscillation of the tube and its distance from the screen. Two shutters, controlled electromagnetically by the oscillating apparatus, allow the right eye to view one image and the left the other, vision being entirely cut off during the time the tube is changing its position. There results, naturally, from the combination of these images an apparently solid reproduction of the object. It is claimed that the method is superior to those employing two tubes, or a tube with two anti-kathodes, as in these cases it is always difficult to obtain equal effects from both tubes or anti-kathodes. It is also stated that the tubes used by the author were not injuriously affected by the vibration.

THE Canadian Department of the Interior has issued a clearly printed map of Manitoba on the scale of an inch to $12\frac{1}{2}$ miles. It will be useful to those desirous of taking up land in the country.

PARTICULARS of the mode of occurrence and removal of a carcase of the mammoth which had been discovered in 1901 in the province of Iakousk, in Siberia, are contributed with illustrations by M. L. Elbée (*La Nature*, May 23). The remains were half embedded in the snow and ice, and there were still preserved the eyes, the mouth, and even the stomach. Measurements showed that the animal was about 3 metres in length and 2 metres in height, and must have weighed about 1000 kg. The specimen has not yet been exhibited in public owing to the great difficulties experienced in preserving the skin.

IN the annual report for 1902 of the State Geologist of New Jersey, Mr. H. B. Kümmel, there is an account of the copper deposits of the State, by Mr. W. H. Weed. Copper minerals occur at many localities in the crystalline rocks and in the Triassic Red Sandstones, but only in the Red Sandstones are they of economic value. In these rocks the ores are almost always associated with basalt, dolerite, and diabase of very uniform chemical composition, and from these basic igneous rocks, in the opinion of Mr. Weed, the copper ores have been derived.

IN the account of the embryogeny of Zamia which Profs. Coulter and Chamberlain present in the *Botanical Gazette*, they show that during this stage of development the features of Zamia are intermediate between those presented by Cycas and the Conifers.

IN the Philippine Islands Government laboratories were organised by the United States authorities in 1901, and Dr. R. P. Strong was appointed director. The first annual report gives evidence of much work carried out under un-

favourable conditions in temporary laboratories. The work of the biological department is mainly pathological, and is concerned with the study of Asiatic cholera and other tropical diseases. New laboratory buildings are announced, in which special facilities will be offered to foreign men of science who wish to undertake research work.

THE Californian red wood, *Sequoia sempervireus*, forms the subject of a *Bulletin* issued by the U.S. Department of Agriculture. Natural reproduction by seedlings is rare, as these require plenty of light, but the writer, Mr. Fisher, shows that effective second-growth is produced by sucker shoots. A brown rot disease affecting the standing tree is described by Prof. von Schrenck, but the cause of the disease which is said to arise in the heart wood has not been determined. Another *Bulletin*, by Mr. Foley, affords good proof of the value of careful lumbering as adopted on the Sewanee University Estate, Tennessee.

IN addition to some half-dozen short excursions to places of interest of easy access, and one long excursion to the north Donegal coast, beginning on July 10, which it has arranged, the Belfast Naturalists' Field Club is offering for competition during the session ending March 31, 1904, nineteen prizes, generally of the value of one pound, and in other cases of ten shillings, for collections of different botanical, geological and zoological objects. The prizes are to be in books or suitable scientific objects. Among the collections asked for may be mentioned the best herbarium of local flowering plants, representing not less than 150 species, with notes on variations adapting the plants to special environments; the algæ of Larne Lough, with an account of distribution; the algæ of Belfast Lough; fossils from the Rhætic and Lias of Ulster; and the best set of twelve photographs illustrative of any one branch of Irish archæology. A prize is also offered for the best original account of the habits of any marine annelid.

AN interesting interim report upon Cape horse-sickness has been published by Dr. Watkins Pitchford, the Government bacteriologist of Natal. In some respects this disease resembles human malaria, for it especially attacks horses kept on low-lying marshy ground, and those animals left to graze all night. In affected districts horses may be moved during the day without contracting the disease. Dr. Pitchford now suggests that a mosquito, probably of the genus Anopheles, is responsible for the conveyance of the infection. He has stalled horses by night in stables protected by wire gauze, or by a smoky atmosphere, in an infected district, with the result that they all remained perfectly well; whereas horses kept around and similarly treated, with the exception of the protection afforded by the wire gauze or smoke, succumbed. He therefore believes that it is established that horses protected from the attacks of winged insects enjoy immunity from horse-sickness.

THE January issue of the *Proceedings* of the Philadelphia Academy contains a list of the polycistid gregarines of the United States, by Mr. H. Crawley, and an account of the habits of spiders, by Dr. T. H. Montgomery.

WE have received three parts (Nos. 10–12) of Manchester Museum *Notes*, in two of which Prof. W. B. Dawkins deals with the older rocks of the Isle of Man, while in the third he describes certain iron implements found in the old "camp" in Bigbury Wood, near Canterbury. These implements prove that the camp belonged to the prehistoric period, and from this it is inferred that the well-known "Pilgrims' Way," which traverses such a large extent of country in the south of England, likewise dates from that epoch.

THE greater portion of the May number of the *Quarterly Journal of Microscopical Science* is occupied by an important paper from the pen of Mr. H. J. Hansen, of Copenhagen, on the genera and species of the myriopod order Symphyla. The first known species was described 138 years ago, and the order is now known to contain at least 100 species. The other contents of this part include an account of the body-cavity and nephridia of the Actinotrocha larva, by Mr. E. S. Goodrich; a description of various acorn-worms (Enteropneusta) from Madras, by Mr. R. K. Menon; and a notice of the radiolarian *Planktonetta atlantica*, by Dr. G. H. Fowler. The latter organism is distinguished from all other members of its group by the possession of a float, a diaphragm, and a single bundle of tubes of communication.

THE *Times* of May 19 contains a notice of the results of the survey of the fishes of the Nile, undertaken by the Egyptian Government, in cooperation with the trustees of the British Museum, which has just been brought to a conclusion, after three and a half years' hard work by Mr. W. S. Loat, who has had charge of the operations. The scheme was due to the initiation of the late Dr. John Anderson, and although, so far as the discovery of new species is concerned, its results have been disappointing, it has yielded important information with regard to distribution. Previous to the survey, the number of species of fish known to inhabit the Nile was about 90; it is now more than 100, Mr. G. A. Boulenger having described 14 new species from among a collection of between 9000 and 10,000 specimens. Mr. Loat carried his survey far up both the Blue and the White Niles, and thus completed the work begun in the early "sixties" by Consul Petherick. It is satisfactory to learn that Mrs. Anderson has made arrangements for the publication of a volume on the fishes of Egypt in the same style as those on the mammals and reptiles.

A USEFUL manual for practical photographers, by Mr. Alfred Watkins, entitled "The Watkins Manual of Exposure and Development," has reached a second edition. The text-book is published by the Watkins Meter Company, of Hereford, and contains much information likely to prove of service to photographers who already have some acquaintance with the subject, as well as to beginners.

THE fourth edition of the "Official Guide" to the Belfast and Northern Counties Railway, which has reached us, will provide the visitor to the north of Ireland with just the information he will want. The guide is liberally supplied with maps and illustrations, and there are notes on places and objects of scientific interest. The book is published by Messrs. R. Carswell and Son, of Belfast, and costs sixpence.

A NUMBER of attempts have been made at various times to introduce standard points on the temperature scale other than the freezing point and boiling point of water, and for high temperature work, especially the standardisation of platinum resistance thermometers, Messrs. Heycock and Neville have recommended the use, as a third standard temperature, of the boiling point of sulphur. The *Zeitschrift für physikalische Chemie* for April 23 contains an account of a very careful determination, by Messrs. T. W. Richards and R. C. Wells, of the position on the international hydrogen scale of a standard temperature intermediate between the freezing point and boiling point of water. As the mean result of twenty-two determinations made with four different thermometers, it was found that the transition temperature at which the monohydrate and the dekahydrate of sodium sulphate were both in equilibrium with an aqueous solution of the salt lay at $32{\cdot}383^\circ \pm 0{\cdot}001$.

The water used was purified by distilling twice and freezing in a platinum vessel, and the sodium sulphate was crystallised until it gave a constant transition temperature.

THE additions to the Zoological Society's Gardens during the past week include a Serval (*Felis serval*) from South Africa, presented by Mr. C. H. Firmin; a Harlequin Elaps (*Elaps fulvius*) from Central America, presented by Captain J. B. Gilliat; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited; a Chinchilla (*Chinchilla lanigera*) from Chili, purchased; a Japanese Deer (*Cervus sika*), a Sambur Deer (*Cervus aristotelis*), a Red Deer (*Cervus elaphus*), a Thar (*Hemitragus jemlaicus*), an American Bison (*Bison americanus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A REPORTED PROJECTION ON MARS.—A Reuter's correspondent at Cambridge, U.S.A., states that the Harvard College Observatory at Flagstaff reports the discovery of a large projection on Mars at 3.35 a.m. (G.M.T.) on May 26. The position angle of the projection is given as 200°.

REPORT OF THE OXFORD UNIVERSITY OBSERVATORY.—From the report of this observatory for the period May 1, 1902, to April 30, 1903, just issued by Prof. H. H. Turner, we learn that of the 1180 plates which had to be measured and reduced for the Astrographic Chart, 1100 are now completed, 170 of them having been finished during the period with which the report deals.

When these measurements are completed it is proposed to undertake the measures of the plates, obtained during the opposition of 1900–1901, of the planet Eros, for the purpose of obtaining a more trustworthy value for the solar parallax, this work having been undertaken as a supplementary labour by the International Astrographic Committee.

Paragraph vi. of the report gives an account of the fortuitous discovery of Nova Geminorum, which possibly would not have been discovered at Oxford but for the fact that the first batch of plates used in photographing the Nova's region for the Chart proved faulty, and thereby rendered it necessary that this zone should be rephotographed. It was whilst photographing the zone the second time that Mr. Bellamy used the Nova as a "setting" star, thereby causing the inquiry to be set on foot, when the plate came to be measured, which led to the happy discovery that the bright star he had used in setting his instrument was a hitherto unknown object.

PERIODICITIES OF THE TIDAL FORCES AND EARTHQUAKES.—In a paper communicated to No. 3, part ii., vol. lxxi. of the *Journal* of the Asiatic Society of Bengal, Mr. R. D. Oldham, of the Geological Survey of India, discusses the relations between the periodicity of the earthquake shocks recorded by a seismograph set up at Shillong, Assam, during the period August, 1897, to December, 1901, and the periodicity of the tidal forces obtaining at that place during the various relative positions of the sun and moon.

After deducing the reasons for expecting the shocks to appear at certain times during the day and night when the tidal force is at a maximum at the place of observation, Mr. Oldham sets out the recorded shocks in a series of tables and curves. On examining these it is clearly seen that there was a real and a very large variation in the diurnal distribution of shocks in Assam during 1897–1901, their greatest frequencies occurring at 10–11 p.m. and 6–7 a.m., and superimposed on this regular but unexplained variation there was a smaller one, which appears to have been due to the tidal stresses set up by the attraction of the sun. If this latter variation is really due to tidal stress, it then appears that the horizontal component of the stress is much more effective than the vertical component, whilst the effects are more dependent on the rate and range of the stress than on its amount.

Mr. Oldham points out that these results are purely provisional, dealing as they do with only a short period of observation in one particular locality, but urges that they are definite enough to warrant the obtaining of a longer record at a place, situated within or near the tropics, where earthquakes are of frequent occurrence.

MISHONGNOVI ANTELOPE-SNAKE CEREMONIES.[1]

IN each of five of the seven Hopi pueblos of Arizona are performed during each year from eight to twelve ceremonies of nine days' duration. The rites of the first eight days are secret, and have certain elements in common; all terminate on the ninth day in a public performance, which has many elements of a gorgeous pageant.

Of the summer ceremonies, those held by the Antelope and Snake societies, which cooperate, are the most spectacular and best known. They alternate in each village annually, with the ceremonies performed by the Drab- and Blue-Flute societies. Thus, in even years, the Snake and Antelope societies perform in Oraibi, Shumopovi and Shipaulovi, and all Flute societies in Mishongnovi and Oraibi; in odd years, the reverse is true.

The time of the Snake-Antelope ceremonies is determined by the date of the last day of the Niman ceremony, which occurs in July, and at which time the Katcinas and masked gods disappear until the following winter.

Four days from this time, certain priests of the Snake-Antelope societies meet in a room, make certain *bahos* or prayer sticks, which are deposited in a shrine on the following morning, at which time the village Crier announces from the house-top the date of the first day of the Snake-Antelope performance, four days hence.

At that time, the chief priests of the Snake-Antelope fraternities meet in their respective *kivas* or underground chambers. During the next four days, the Antelope priests gather in constantly increasing numbers in their *kivas*, make *bahos*, indulge in fraternal smoking, and on the fifth day, prepare on the floor of their *kiva* a sand picture and erect their altar.

During this time the Snake priests have been engaged in a ceremonial hunt for snakes, scouring the country to the north on the first day, on the west on the second, &c.

Very early on the sixth, seventh, eighth and ninth days the Antelope priests gather about their altar, and, reinforced by the chief priest of the Snake society and two personages representing the Snake Youth and Antelope Maiden of the legend, sing eight traditional songs. These performances are the most beautiful and sacred of the entire ceremony. On the eighth and ninth days of this singing ceremony there is the added element of two Snake men, dressed as Kalehtaka or Warriors, who perform with the bull-roarer and lightning-shooter, after which they, with an Antelope priest and fifty or sixty young men of the village, repair to a spot in a plain far below the mesa, where, after the deposition of *bahos* and the laying of cloud symbols by the Antelope priest, there begins a spirited and exciting race on the part of the young men to the summit of the mesa. The winner of the race on each morning receives from the hands of the chief of the Antelope priests a small netted gourd containing water from the medicine bowl, which has been fertilised by smoke, which he later deposits in his field.

On the afternoon of the eighth day occurs a public performance in the plaza, participated in by all the Antelope and Snake priests, properly costumed, at which time the Antelope men in turn carry in their mouths a corn-husk packet, receiving it from the *kisi* or booth of cottonwood especially erected in the plaza for this purpose.

On the ninth day occurs the most sacredly guarded event in the Snake *kiva*. At noon the snakes, numbering from sixty to eighty, one-third or one-fourth being rattlesnakes, which have been guarded in this *kiva* in earthenware jars, are placed in one large bag. The Snake priests gather along one side of the *kiva* in line, seated upon stones. In front of the chief priest is a bowl containing medicine water.

1 "The Mishongnovi Ceremonies of the Snake and Antelope Fraternities." By George A. Dorsey and H. R. Voth. Field Columbian Museum Publication 66, Anthropological Series, vol. iii. No. 3.

The Snake priests begin shaking their snake whips, beating time to the set of traditional songs which they now sing; the chief priest now plunges his hands into the sack and grabs as many snakes as possible, and thrusts them into the medicine bowl in front of him, then violently casts them upon the floor of the *kiva* immediately in front of the priests, the floor having been covered with a two-inch layer of sand. This continues until all the snakes have been washed, the priests herding the snakes with their whips, hands and bare feet.

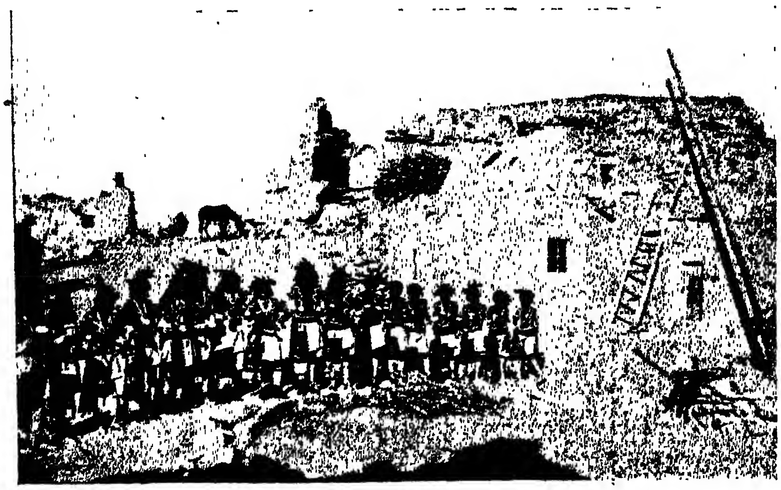

FIG. 1.—Antelope Priests leaving the Kiva.

The remainder of the afternoon is spent by the priests of both fraternities in properly costuming themselves for the final and public performance, which begins as the sun is about to sink behind the San Francisco Mountains in the west.

In the meantime three or four naked boys have been herding the snakes in a corner of the *kiva* and playing with them, tossing them, one to another, with a reckless abandon which at first is startling and finally commonplace.

The hour having arrived for the dance, the snakes are again gathered up, thrust into a sack, and carried by one of the priests to the *kisi* in the plaza, within which he secretes himself. The Antelope priests are first to leave their *kiva*, and proceed in single file, led by their chief priest, to the plaza, which they circle four times and halt in line in front of the *kisi*. They are closely followed by the Snake priests, who perform similar evolutions, halting also in front of the *kisi*, but facing the Antelope priests. The appearance of the men at this time, as they proceed to the plaza, is very striking and beautiful, forming a sight not to be forgotten. In this attitude they sing several songs, the time to which is kept by the snake men with their snake whips and long black *bahos*, and by the antelope men with their peculiar Antelope rattles. As the singing proceeds the positions of the bodies of the men are changed from time to time, in accordance, presumably, with the movement of the drama. As the end of a certain song is reached the man at the head of the line of the Snake priests leaves his position, passes down to the centre of the line of the Antelope priests and in front of the *kisi*, where he stops, passes his hand in between the Antelope priests, and receives from the priest within the *kisi* a snake, which he grasps with his lips, at a position about four inches from the snake's head. He is called the "carrier." He is followed by a second Snake priest called the "hugger," who passes his arm over the first priest's shoulder and, with his snake whip, guards the "carrier's" face from the snake's head. The "hugger," in turn, is followed by the third Snake priest, known as the "gatherer," whose duty it is to pick up the snake should it wriggle from the "carrier's" mouth; and so the entire line of Snake priests files by the *kisi*, every third man receiving a live snake, which he places in his mouth. Thus they proceed in an elongated circuit, each "carrier" dropping his snake as he again approaches the *kisi*, where he receives a fresh snake. By the time all the snakes have been passed out, the hands of the "carriers" are well filled with the wriggling snakes.

A circle of white meal is now spread upon the ground in front of the Antelope priests, into which the "carriers" cast the snakes in one heap. The Snake priests now run by the snakes, and each man plunges both hands into the mass, and, grasping as many as he can, starts off down the mesa-side, the first man to the north, the second to the west, and so on, until all the snakes have been removed, each priest depositing his snakes together with a *baho* half-way down the side of the mesa.

The antelope priests, in the meantime, have again circled the plaza four times, and have returned to the roof of the Snake *kiva*, where they and the now returning Snake priests drink freely from the great bowls of emetic which produces violent vomiting. The priests now repair to their respective *kivas*, where they disrobe. In the Snake *kiva* there is an additional discharming ceremony, followed by a feast, this being the first food the chief priests have taken for four days, and the other priests since the preceding day.

FIG. 2.—Line of Snake Priests leaving the Kiva.

The four days following this public performance are devoted largely to sports and games of children, in which struggles for prizes of corn, melons, &c., together with rabbit hunts, play an important part.

The performances just described in outline only dramatise the legend of the Snake clan. The entire movement of the ceremony has for its immediate and ultimate object the

preparation of a medicine or magic which will be so efficacious as to overcome the magic of the rain clouds, and cause them to give up their stores of water; for the August suns in the south-west are rapidly drying up the corn, which, without rain at this period of the year, would be a failure. But when it is remembered that the Hopi live almost entirely upon vegetable products, of which corn forms almost 80 per cent., it will readily be understood that, should the combined efforts of the two sets of priests be not successful, famine must be the result. As each snake is released with a *baho*, it bears with it prayers which it is supposed to transmit to the great plumed serpent, who has influence with the rain gods of the four world quarters. It may be added that the fundamental element of nearly all Hopi ceremonies is the production of a magic which will overcome the magic of the rain clouds.

So far as the writer is aware, no Hopi has ever died as a result of a snake-bite during these ceremonies. Nor has he ever seen a priest bitten by a snake. He is positive that nothing is done to render the snakes harmless. Nor do the Hopi have any antidote for the poison of the rattle-snake. The Hopi seems thoroughly to understand the rattle-snake, and is cautious never to attempt to pick him up when in a coiled position. The Snake priest always carries with him his snake whip, which he shakes over the snake when coiled, as he is about to pick it up in the fields during the hunt, or in the *kiva* as he transfers it from the snake bag to the receptacle, or as he herds the snakes in the *kiva*, or picks them up on the plaza. Rarely is a snake seen coiled, its ambition being to escape.

GEORGE A. DORSEY.

FIG. 3.—Priest using the Snake Whip preparatory to picking up a Snake.

WERE THE FERN-CYCADS SEED-BEARING PLANTS?

THIS was the burden of a preliminary paper read at the Royal Society on May 7 by Prof. F. W. Oliver and Dr. D. H. Scott, F.R.S., entitled "*Lagenostoma Lomaxi*, the seed of Lyginodendron."

During recent years the petrified remains of many fern-like plants from the Carboniferous rocks have received close attention, with the striking result that the internal organisation of not a few shows a marked approach to that characteristic of the Cycads, the most primitive of existing seed plants. These plants, therefore, whilst retaining the outward form of ferns, are in reality transitional types. For convenience, these plants, which include the genera Heterangium, Lyginodendron, Medullosa, and many others, have been placed in a special group, the Cycadofilices or Fern-Cycads. The recognition of this group is one of the more interesting results that has accrued in recent years in fossil botany, and the view that the Cycadofilices are the remains of a natural bridge connecting the ferns and the Gymnosperms has received wide support.

In no case, however, had the fructification of any Fern-Cycad been definitely recognised, hence it remained an open question whether the Cycadean advance which was so marked a feature of the vegetative organs found its counterpart in the reproductive process.

In the paper under notice the authors bring forward what they regard as adequate evidence for assigning a seed to Lyginodendron, perhaps the best known of all Cycadofilices, owing to its admirable preservation and very common occurrence in the calcareous nodules of the Lower Coal-measures.

Numerous detached seeds are known from the Palæozoic rocks, but in no case has it been ascertained by what plants these seeds were borne, with the exception of certain forms which have been traced to the extinct family of the Cordaiteæ, and the curious seed-like fructifications of two Lycopods, Lepidocarpon and Miadesmia. The rest, although of great interest in the details of their organisation, have remained unassigned, being without traces of their origin, like fallen acorns in a forest.

In the case, however, of the seeds placed by Williamson in his genus Lagenostoma, a re-examination has revealed unexpected points of agreement between the structure of the envelopes of certain of these seeds, on the one hand, and the vegetative organs of Lyginodendron on the other. It appears that the seed named *Lagenostoma Lomaxi* after its discoverer, and occurring chiefly at Dulesgate, in Lancashire, is sometimes still attached to its pedicel, and is found enclosed in an envelope or cupule springing from the stalk just below the base of the seed, and extending above the micropyle, at least in young specimens. The cupule, in its relation to the seed, which is quite small,

not larger than a pea, may be compared to the husk of a hazel-nut in miniature.

Both cupule and stalk bear numerous capitate glands, some stalked, others sessile, which present the closest agreement in size, form and structure with the glands which occur on the vegetative organs of Lyginodendron. It is the agreement between these glands, so close as to amount to identity, that forms the basis of the attribution of the seed to Lyginodendron. There is no other known plant from the Coal-measures with glands at all similar, nor is it likely that any unknown Gymnosperm should exactly resemble Lyginodendron in these characters. The vascular strands which traverse stalk and cupule present the closest agreement with those of Lyginodendron, and these and other characters go to strengthen the conclusion drawn from a comparison of the glands, and further support the attribution. The evidence will, of course, be weighed by botanists. Should it find acceptation, we have the following position. Lyginodendron, a fern-like plant with certain Cycadean characters, possessed seeds (on its leaves, so it may be inferred from the structure of the stalk and cupule) as fully characterised as those of any known Palæozoic gymnosperm. It retains, so far as its vegetative structure is concerned, the intermediate position already assigned to it, but whereas the fern-like characters have hitherto seemed to preponderate, the discovery of the seed inclines the balance strongly on the Gymnospermous side. The germ of the present discovery dates from the time when it became apparent on anatomical grounds that Lyginodendron was a transitional type. Dr. Scott in his published writings had already prepared the way, and the position now gained is the logical sequel. Nor is it likely that Lyginodendron stood alone; we must be prepared to find, what has long been recognised as a possibility, that many of the plants grouped under Cycadofilices already possessed seeds, and thus that a considerable proportion of the so-called "fern-fronds" of the Palæobotanist really belonged to seed-bearing plants. The status of these "ferns" may be expected to take many years to unravel, owing to the difficulties that will be encountered in discriminating between such as bear true fern-sporangia and those the sporangia of which are really the pollen-sacs of Gymnospermous plants, and in allocating the numerous impressions which are quite sterile. It is premature to speculate how far back in the fern-series a seed habit obtained, but the results of further investigations in this field will be awaited with interest.

"TABLOID" PREPARATIONS FOR PHOTOGRAPHY.

THERE is probably no one who has reason occasionally to take a photograph, whether for simple pleasure or for scientific or business purposes, without having at command a well-equipped photographic laboratory, who does not consider the preparation of the various solutions required as a messy, troublesome and tedious performance. And the getting of some of the chemical substances in a fit state for use is a very real difficulty, only to be got over in some cases by procuring the original packages or bottles as issued by the manufacturer, and containing perhaps twenty times as much as is required. We have known several cases where so common a substance as sodium sulphite has been obtained only after seeking for it at several druggists, and other cases where the work was spoilt by reason of the gross impurity of the material.

These and similar difficulties are now matters of the past for those who use the "tabloid" preparations of Messrs. Burroughs, Wellcome and Co. Instead of a large bottle of stuff awkward to manipulate because either the substance is in hard lumps or light feathery crystals, one has a little bottle of little pills that need no weighing, because the contents of each are indicated on the label. In the majority of cases each tabloid has in it the quantity of material needed for one ounce of solution, so that any bulk can be made up without the possibility of error in calculation. The tabloids required are put into the measure glass, water added, stirred a little or crushed with a glass rod, and the solution is ready for use, with the advantage that it is fresh, and made with materials that can be relied on.

In many cases the requisite chemicals are mixed in the one tabloid, sulphite, alkali, and bromide, for example in developers, but there are no secret formulæ, as the contents of every tabloid are clearly set forth on the label. The formula, if necessary, can be modified to any extent by adding to it a tabloid of one or the other ingredients; or, if preferred, tabloids of simple unmixed substances may be used throughout.

So far as variety goes, practically everything that is required in photographic practice is supplied, including even such rarely used chemicals as potassium percarbonate and ammonium persulphate. There is a large selection for making gold baths for the toning of prints, and potassium ammonium chromate is supplied in 24-grain tabloids for sensitising carbon tissue. Ferrous oxalate and mercuric chloride are the only two omissions that we note; perhaps there is some difficulty with regard to these.

It appeared not unlikely that some of the chemicals might show signs of deterioration from their manipulation in the preparation of the tabloids, but those that we have tested have proved unexceptionable in quality. These preparations are worthy the attention of even the best equipped photographer working at home in his own laboratory, particularly with regard to the chemicals that are rarely required.

A NEW INDEX OF APPLIED SCIENCE.

WE have received a copy of the first issue of a new monthly periodical[1] published at Brussels. The title, *Index of the Technical Press,* appears on it in the three languages French, English and German. The object of the publication is to supply a monthly index of articles of general interest appearing in the technical Press throughout the world, and giving the title with a brief explanation, the name of the author, the origin, the date of publication, and the length. In the case of articles appearing in the English, French, and German papers, these details are given in the languages in which they originally appeared. In the case of articles printed in other languages they are translated into French.

One very good characteristic of the publication is that it is printed on one side of the paper only, and in a convenient form for cutting out and pasting on cards for use in connection with card indices.

The publishers undertake to supply cuttings from the original papers of most of the articles indexed, at prices indicated by a letter affixed to each entry. Translations can also be obtained on a fixed scale. Such a publication should be of considerable value if the scheme is carried out with completeness, and the subscription price of five francs per annum is not a heavy one. Much, however, will depend on the interpretation given to the expression "general interest."

The greater part of the issue is taken up with entries of engineering articles under various headings; some of these cover rather a wide field—electrical engineering, for example, forms one of the sections, without any subdivisions.

Besides engineering articles, there are sections devoted to statistics, political science, political economy, law, legislation and jurisprudence, administration, constabulary, insurance and partnership, commerce, communication and transport, mathematics, astronomy, physics, chemistry, geology, medicine. Various trades and manufactures are also included.

The "brief explanation" promised is confined to very slight extensions of the title in some cases, so that the only guide to the value of an article is the name of the author and that of the paper from which it is taken. This, however, if the indexing is really comprehensive, should be of considerable value, more especially with regard to subjects in which systematic abstracts are not obtainable.

Rather numerous errors are made in printing the English and German entries, especially in the former. They are not of a character to cause any inconvenience to those familiar with the languages, but they are unsightly, and their occurrence might easily be obviated by the employment of a proof reader familiar with the languages.

G. W. DE T.

[1] *Index of the Technical Press.* (20 Rue de la Chancellerie, Brussels.)

TRIASSIC CEPHALOPODS.

ALL who are interested in the invertebrata of the Trias will be pleased to see the supplement recently issued to "Die Cephalopoden der Hallstätter Kalke," by Dr. Edmund Mojsisovics (*Abhandlungen der k.k. Geologischen Reichsanstalt*, Band vi., 1902). The first volume of this detailed and beautifully illustrated memoir, published in 1873 and 1875, contained 174 pages of text and 70 finely executed lithographic plates. The second volume appeared in 1893, and extended to 835 pages and 130 plates. The part now published is a supplement to the first volume, and continues the paging from 175 to 356, while the plates are numbered from 1 to 23 as supplementary. It is somewhat difficult for geologists familiar only with the English Trias to realise the richness of the fauna described in this memoir, which, for the sufficient illustration of the Cephalopoda alone, needs 223 large quarto plates. The author speaks in the preface of the somewhat primitive nomenclature of the earlier parts of the first volume, but the most forward student will have nothing to complain of in this direction in the present supplement, unless it be the use of such impossible names as Pompeckjites. Some interesting remarks are made on the subdivisions now adopted for the "Hallstätter Kalke," and a table of these is given on p. 345. Among the forms of Cephalopods here described, none perhaps are more remarkable than the primitive types included in the Belemnitidæ. In transitional deposits such as the Trias one expects to find the lingering of antique forms and the foreshadowing of types yet to come; but it is a little startling to find the Carboniferous genus Pleuronautilus so nearly associated with such forms as Rhacophyllites, which so strongly reminds us of the Liassic *Phylloceras heterophyllus*. The author is to be congratulated on the successful completion of this monumental work, which has engaged his attention for so many years, and, by this supplement, is brought fully abreast of the present time.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Romanes lecture will be delivered by Sir Oliver J. Lodge, F.R.S., in the Sheldonian Theatre on Friday, June 12, at 5 p.m. The subject of the lecture is "Modern Views on Matter."

On Saturday last Prof. Tylor, F.R.S., was elected an honorary fellow of Balliol College, of which he has been a member since his appointment as Keeper of the University Museum and reader in anthropology in 1883.

Last week's *Gazette* contained the report of the museum delegates for 1902. Considerable additions have been made, particularly to the Pitt Rivers and Hope collections. An important change in administration took place after Prof. Tylor resigned the keepership, this office being abolished and replaced by a secretary to the museum delegates. Prof. Miers, F.R.S., was appointed to the new position. During the past year three new laboratories have been added to the chemical department, and an electric installation has been put into the museum

The Junior Scientific Club held a conversazione in the museum on the evening of Tuesday, May 26. Lectures were given by Sir David Salomons, Bart., on "Motor Cars," by Prof. Arthur Thomson on "Man's Cranial Form," and by Prof. Miers on "Klondyke." Among the exhibits were an excellent demonstration of the properties of radium by Mr. F. Soddy, a show of collotype and three-colour printing from the Clarendon Press, an improved form of capillary electrometer by Mr. H. S. Souttar, photographs of the new star in Gemini by Prof. Turner, a collection of living British fresh-water fish by Mr. Morison, a demonstration of the principles of wireless telegraphy by Mr. Littlehailes and Mr. Lattey, and a collection of apparatus from the Cambridge Scientific Instrument Company and the Magdalen College Laboratory.

CAMBRIDGE.—Dr. Chase, president of Queens' College, has been re-elected Vice-Chancellor for the ensuing academical year.

Mr. F. W. W. Griffin, King's, has been appointed to the university table in the Plymouth Marine Biological Laboratory.

In the mathematical tripos, part i., sixty-five men and eighteen women have acquitted themselves so as to deserve mathematical honours.

The memoirs of Mr. J. Parkinson, advanced student of St. John's College, on the geology of Tintagel and Davidstow, and on the rocks of Guernsey, have been adjudged to be "of distinction as a record of original research."

DR. THOMAS SLATER PRICE has been nominated to succeed Mr. Woodward as director of chemical studies at the Birmingham Municipal Technical School.

AN exhibition of practical work executed by candidates at the technological and manual training examinations of the City and Guilds Institute will be opened at the Imperial Institute on Thursday, June 11, at 3 p.m., by the Marquess of Londonderry, K.G.

Science announces that Prof. William H. Brewer has resigned the professorship of agriculture at Yale University and has been appointed professor emeritus. At Cornell University Prof, T. F. Hunt, dean of the Agricultural College, of the Ohio State University, has been appointed professor of agronomy, and Dr. B. F. Kingsbury has been appointed assistant professor of embryology.

ON the occasion of the commemoration day proceedings at Livingstone College, Leyton, on June 10, the Bishop of St. Albans will preside. Livingstone College has rendered valuable services, not only to missionaries, but also to many travellers in unhealthy regions, and it is hoped that the present opportunity will lead to much greater interest being taken in the work carried on under its auspices.

IT is worthy of note that in connection with a short course of popular lectures on nature-study just given by Mr. C. Carus-Wilson at Ramsgate and Margate, excursions were arranged to places of geological interest in the neighbourhood. Field-work and personal observation of natural objects and phenomena are essential in the study of nature, and it is to be hoped that wherever popular lectures are given on natural science subjects, outdoor work will be arranged in connection with them.

THE draft charters incorporating universities in Manchester and Liverpool have, the *Times* reports, been approved by the Privy Council and laid before Parliament. In the case of Manchester, the charter provides that the University shall be called "the Victoria University of Manchester." A description is given of the powers conferred upon the University relating to such matters as the granting and conferring of degrees, the granting of diplomas, the provision of instruction in such branches of learning as the University may think fit, the examination and inspection of schools, and the affiliation of other institutions. The authorities of the University will be the Chancellor, the Vice-Chancellor, two Pro-Vice-Chancellors, the Court, the Council, the Senate, the Board of Faculties, and the Convocation, besides a treasurer and other proper officers. In the case of Liverpool, the charter provides that the University shall be known as "the University of Liverpool." It is provided that Lord Derby shall be the first Chancellor of the University, and Mr. A. W. W. Dale, now principal of University College, Liverpool, the first Vice-Chancellor. The supreme governing body of the University is to be the Court, and the governing body and executive of the University is to be the council; and the Senate, consisting of the Vice-Chancellor, the deans of all the faculties, all the professors of the University, and the librarian, will, subject to the statutes of the University and the control and approval of the council, regulate and superintend the education and discipline of the University.

IT is announced in the *Times* of May 28 that the council of the Yorkshire College has agreed upon the principles upon which the charter for the proposed new Yorkshire University should be based. These are that the Yorkshire College be merged in the University; that the University be founded on a non-federal basis, but that it be empowered to affiliate other institutions; and that the University be governed by a court of governors and by an executive

council. Substantial agreement has been arrived at between the three colleges, which have constituted Victoria University, as to a common matriculation examination for all the three Universities of Yorkshire, Manchester, and Liverpool, and provision has been made for a joint board to be constituted from the three Universities to deal with the question. The additions to the staff and equipment of the college essential to the proper carrying on of an independent University will, it is thought, require a *minimum* additional expenditure of about 7000*l*. a year, while extensive additions will also be required to the college buildings. The coal-owners of Yorkshire have decided to erect a separate building for the mining department, and have collected a sum of 5500*l*. for the purpose. The council of the college is desirous also of completing the main block of the college, and it is estimated that this would cost about 60,000*l*. Three friends of the college have each promised 5000*l*., while a fourth has promised 2000*l*. The Clothworkers' Company of London offers to transfer to the new University as its absolute property the whole of the buildings and equipment of the textile industries, dyeing and art departments, which are at present held in trust by the college for the Clothworkers' Company. Attached to the offer is a condition that these departments shall be recognised as integral parts of the University. The Company has also promised to grant in perpetuity to the University for the maintenance of these departments an annual sum of not less than 4000*l*. This means a gift to the University of a capitalised sum of upwards of 200,000*l*.

WE learn from the *Pioneer Mail* that the Government of India has addressed to the Bombay Government a long letter on the subject of the proposed Tata endowment of a research institute for India. It is in the main an explanation of the delay of four years which has occurred in giving effect to the scheme. As has been already explained in these columns, the scheme owes its origin to the munificent intentions of Mr. J. N. Tata, who in 1896 proposed to vest in trustees properties in Bombay, representing a capital of thirty lakhs of rupees, in order that the net income, amounting to some 8000*l*., might be applied towards the endowment of a research institute for India. The proposal soon assumed the form of an Imperial teaching university, intended to train Indian graduates in scientific research, to confer degrees, and to select the best students for further training in Europe and America. Mr. Tata was later asked to consider whether the original scheme was not too ambitious, and whether it might not be proceeded with, so far as funds permitted, leaving the further development to come with the growth of income. Mr. Tata met a small conference of educational experts, and with them defined the general principles to be kept in view in launching the scheme. Sir William Ramsay was invited to visit India to advise, and the help of other experts was obtained. Much delay has been caused by a consideration of numerous recommendations received, but we are glad to know that financial difficulties appear to have been overcome, and that legislation will probably soon follow with a view to provide India with an institution for higher scientific instruction. The institute is to be located at Bangalore, and the Mysore durbar, in addition to making a free grant of land, has undertaken to contribute 3333*l*. per annum for a period of ten years. The Government of India is prepared to make a similar annual subsidy. This will raise the income to 15,000*l*. per annum, which exceeds by 1000*l*. the highest estimate of necessary expenditure framed by Sir William Ramsay. The Government also proposes to contribute one lakh of rupees towards the cost of the construction and equipment of the necessary buildings. The institute is to comprise a department of chemistry, a department of experimental physics, and a department of experimental biology.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 14.—"The Combination of Hydrogen and Chlorine under the Influence of Light." By P. V. **Bevan.** Communicated by Prof. J. J. Thomson, F.R.S.

The first point studied in this investigation was the initial expansion, or Draper effect, when light is allowed to fall on a mixture of hydrogen and chlorine. This expansion was shown to be due to heat developed by the combination of the hydrogen and chlorine to form hydrochloric acid. The heat effect was measured by the change in resistance observed in a fine platinum wire sealed through the bulb in which the gas mixture was exposed to light. The investigation then considers the period of induction of Bunsen and Roscoe, and the effects of various intensities of light on the rate of combination. Experiments were also made on the effect of illuminating chlorine before mixing with hydrogen, and the original observation of Draper—that the combination takes place more readily after this preillumination—was confirmed. If, however, the gases be bubbled through water after preillumination of chlorine, this effect is destroyed, and the gases behave like the ordinary mixture. To obtain evidence of an intermediate compound, the gases were submitted to sudden expansion producing supersaturation. When the gases were dust free a nucleus-forming substance occurred after illumination, so that on the expansion a cloud was formed when the supersaturation reached a certain amount. In the non-illuminated gas mixture no cloud-producing substance could be observed with yellow light. This cloud is produced in chlorine alone. In the mixture of hydrogen and chlorine the cloud appears before any hydrochloric acid is formed. The theoretical part of the paper considers the action as taking place in three stages, combination to form complex molecules containing hydrogen chlorine and water molecules occurring, and then a break down of this complex system giving hydrochloric acid and water. The view thus taken explains the chief features of the induction period, and can be extended to apply to other similar actions where a catalyser is necessary for the progress of the action.

"On the Photo-electric Discharge from Metallic Surfaces in Different Gases." By W. Mansergh **Varley,** M.Sc., Ph.D. Communicated by Prof. J. J. Thomson, F.R.S.

The object of the experiments was to study the effect of the pressure and nature of the gas with which a metal surface is surrounded upon the magnitude of the photo-electric current from that surface, the method used being to draw the complete curves connecting the current and the potential difference at each pressure or in each gas examined, keeping the intensity of the ultra-violet illumination and the other conditions unaltered.

A suitable source of ultra-violet light which would remain constant in intensity while long series of observations were being taken was ultimately found in the spark between iron terminals in an atmosphere of pure dry hydrogen. The spark gap was in parallel with three Leyden jars in the secondary circuit of an induction coil used as a transformer. The photo-electric currents were measured from a metal surface placed a few millimetres behind a fine gauze, through which the light passed, and which served as the positive electrode. A brass vessel, with a quartz window, to admit the light, served to contain the electrodes.

Series of curves were obtained showing the relation between the photo-electric current and the potential at pressures ranging from 760 mm. to 0·0014 mm. They show that down to pressures of about 1 mm. no true saturation currents exist, the currents always increasing with the potential, but less rapidly for a certain range of potential gradients than for lower or higher potential gradients, while at pressures below the critical pressure true saturation currents exist.

Curves connecting the potentials and corresponding photo-electric currents in air, carbon dioxide, hydrogen and carbon monoxide at various pressures were also obtained, and it was shown that the curves could all be explained on the ionic theory of conduction, both qualitatively and quantitatively. Zinc, platinum and aluminium electrodes were employed.

"On the Discovery of a Species of Trypanosoma in the Cerebro-spinal Fluid of Cases of Sleeping Sickness." By Aldo **Castellani,** M.D. Communicated by the Malaria Committee of the Royal Society.

The author states that he has found trypanosomes to be present in the cerebro-spinal fluid in twenty out of thirty-four cases of sleeping sickness examined; in two of the cases trypanosomes were also found in the lateral ventricles, and in one in the blood taken from the finger. The cerebro-spinal fluid was obtained by lumbar puncture, and as the trypanosomes are not numerous, it was first centri-

fugalised and the deposit examined microscopically. This species of trypanosoma seems to differ from that found in human trypanosomiasis (*T. Gambiense*, Dutton) by being less motile, by the micro-nucleus being situated nearer the extremity, and by the vacuole being larger. Should it prove to be a new species, the author suggests that it should be named the *Trypanosoma Ugandense*. The author had previously isolated a streptococcus in this disease; he now suggests as a working hypothesis that sleeping sickness is due to a trypanosoma, and that in the last stages there is a concomitant streptococci infection.

In a note to this communication the secretary of the Royal Society (Sir M. Foster) states that a telegram has been received from Colonel Bruce, who is continuing Dr. Castellani's investigations in Uganda, announcing that he has found trypanosomes in the cerebro-spinal fluid in every one of thirty-eight cases examined, and in the blood in twelve out of thirteen cases.

Physical Society, May 22.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Mr. J. **Stöttner** gave an exhibition of Nernst lamps, showing their development from the experimental form up to the most recent types. The oxides used for the glowers are thoria, zirconia, and other rare earths thereto related, such as oxides of yttrium and cerium. A paste of these is formed, and small rods or tubes are pressed through a suitable nozzle. These are hardened and cut into small lengths, and practically the principal part of the lamp is finished. The chief difficulty in the practical lamp is in the design of a durable automatic heater to heat the filament up to conducting point. A number of automatic arrangements which have been designed for disconnecting the heater were shown. Another important part of a Nernst lamp is the bolstering resistance, which in its final development consists of a thin iron wire sealed in a glass bulb filled with hydrogen gas. If a lamp is used without a bolstering resistance, as soon as a certain critical potential is reached the current increases, at first slowly and then quicker and quicker, the potential remaining constant, until the lamp burns itself out.—Mr. T. H. **Blakesley** gave an exhibition of a diagram for single-piece lenses. The properties of a single-piece lens are determined by four factors:—the two radii of curvature, the thickness of the lens, and the value of the refractive index of the material of which it is composed. In the case of a lens of a particular thickness made of a material of definite refractive index, the variables reduce to two, namely, the ratios of the radii of curvature to the thickness of the lens. Any property of the lens requires a relation between these quantities. It is therefore possible, for any property, to draw a curve, with r_1/d as ordinates and r_2/d as abscissæ, such that any point on the curve represents a lens having that property. Mr. Blakesley has drawn curves representing several properties. Where two curves cut there is a point which gives a lens having the properties due to both curves. By means of such a diagram various lenses have been constructed, and three of them were shown at the meeting. Of these, one was equivalent to a Huyghens eye-piece and another to a collimator.—A paper on an instrument for measuring the lateral contraction of tie-bars, and on the determination of Poisson's ratio, was read by Mr. J. **Morrow**. Practical methods for the determination of the ratio of lateral to linear strain in a tie-bar may be divided into three classes. First, those in which two coefficients of elasticity are determined and Poisson's ratio calculated; second, those depending on the deformation of the section of a beam; and lastly, methods by which the two strains are actually measured. The experiments described in the paper belong to the third. From a table of results, it appears that the average values of σ are for mild steel 0·275, Sheffield spindle steel 0·276, wrought iron 0·277, Muntz metal 0·341, and drawn copper 0·327. The specimens were not annealed, and were mostly about one inch in diameter. For the experiments on cast iron, two series of specimens were carefully cast of material of good average quality. These were loaded several times in order to eliminate permanent set. The first series gave an average value $\sigma = 0·246$ and the second $\sigma = 0·252$.

Chemical Society, May 20.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The conditions of decomposition of ammonium nitrite, by V. H. **Veley**. The decomposition of ammonium nitrite into nitrogen and water proceeds according to the general law $\log. A/A-x = a\theta$, whether the reaction follows its normal course or is accelerated by the addition of another substance. The decomposition is either impeded or stopped by ammonia, aliphatic, benzenoid or pyridine amines and aromatic hydrazines, and to a less degree by oximes, but is accelerated by aliphatic amides.—Freezing point curves for some binary mixtures of organic substances, chiefly phenols and amines, by Dr. J. C. **Philip**. When freezing point curves for mixtures of two substances are constructed two types are obtained:—(*a*) a curve consisting of two branches, starting from the freezing points of the constituents and cutting each other at a eutectic point; (*b*) the two branches are cut by a third intermediate curve, which may sometimes have a summit. Examples of the latter type have been found for the systems *phenol—urea*, p-*cresol—aniline*, *phenol—α-naphthylamine*, *phenol*—p-*toluidine*, *α-naphthol*—p-*toluidine*, *phenol—picric acid*.—Isomeric partially racemic salts containing quinquevalent nitrogen. Part xi. Derivatives of *dl*-methylhydrindamine and *dl*-*neo*-methylhydrindamine. Isomeric salts of the type $NR_1R_2H_3$, by G. **Tattersall** and F. S. **Kipping**. A description of these compounds was given.—The action of liquefied ammonia on chromic chloride, by W. R. **Lang** and C. M. **Carson**. In this reaction a salmon-coloured powder is produced from which water extracts two unstable, crystalline compounds with the formulæ $Cr_2Cl_6,12NH_3,2H_2O$ and $Cr_2Cl_6,10NH_3$.—Note on the action of methylamine on chromic chloride, by W. R. **Lang** and E. H. **Jolliffe**. The reaction is similar to the foregoing, the product being a pink substance of the composition $Cr_2Cl_6,10CH_3.NH_2$.—Cholesterol, by R. H. **Pickard** and J. **Yates**. The oxidation and hydrolytic products of cholesterol obtained from gall stones have been studied; among the former is arachidic acid.—Sulphocampholenecarboxylic acid, by Messrs. **Hardy** and **Lapworth**.—Optically active esters of β-ketonic and β-aldehydic acids. iii. Azo-derivatives of menthyl acetoacetate, by A. **Lapworth**.—Hydrogen cyanide in fodder plants, by J. C. **Brünnich**. The observation of Dunstan and Henry that the amount of prussic acid producible from the Sorghum plant increases as the plant matures and decreases after the production of seed has been confirmed by a series of determinations of the prussic acid obtainable from manured and unmanured plants at all stages of growth.—The chemical reactions involved in the rusting of iron, by Prof. W. R. **Dunstan**, F.R.S. It is shown that the presence of liquid water and oxygen is necessary for the formation of iron rust; this action is merely accelerated, not conditioned by the presence of carbon dioxide. No rusting occurs when pure iron is kept in presence of oxygen and water vapour at constant temperature; the rusting of iron is prevented by the presence of solutions of such salts as decompose hydrogen peroxide, whilst its formation is not inhibited in solutions of salts in presence of which hydrogen peroxide is stable. The deduction is therefore drawn that hydrogen peroxide is the active agent in the production of iron rust.

Geological Society, April 29.—Mr. J. J. H. Teall, F.R.S., vice-president, in the chair.—The age of the principal lake-basins between the Jura and the Alps, by Dr. Charles S. Du Riche **Preller**. The author deals with the question reserved from a preceding paper, that is, to which subsequent period the formation of Swiss lake-basins should be assigned. By the light of further recent investigations in the different localities, he first considers the conditions of the Zurich lake-valley, and then applies his conclusions to the other principal lake-basins lying in the same zone along the edge of the Alps. Evidence is adduced to show that the deep-level gravel-beds in the Limmat Valley near and below Zurich are essentially fluviatile, composed of the characteristic Alpine material of the Rhine and Linth drainage-areas, and similar to the gravel now carried by the River Sihl. These gravel-beds rest upon Glacial clay of the second glaciation, which fills the Molasse-bed of the valley to a great depth, and are overlain by the moraine-bars of the third glaciation, the latter being overlain by the post-Glacial alluvia of the Sihl. On mechanical grounds, it is difficult to conceive how glaciers could either bridge or completely fill with ice such extensive basins as those of the principal Alpine lakes. As regards the more recently enunciated

argument of the Deckenschotter and overlying gravel-exposure in the Lorze Valley, apart from the difficulty of differentiating the second and third glaciation materials in that locality, it is hazardous to deduce from a local phenomenon, and more especially from any dip of loose gravel, the date of the zonal bending extending over more than 200 miles along the edge of the Alps. The author suggests that the deep-level Limmat gravel beds were deposited by a river during the second inter-Glacial period; that the lowering of the valley floor was initiated in the course of the third glaciation; that the zonal subsidence continued throughout the retreat of the ice; and that the simultaneous formation of the lake-basin should be assigned to the end of the Glacial period. The same arguments apply also to the origin and age of the other principal zonal lake-basins. In his view, the position and depth of these basins, as well as the intervening ground, point to the probability that the bending took place not only along one line, but along several, that the bending was by no means of uniform depth, and that therefore the Alps did not subside as a rigid mass, but that the zonal bending along their edge merely extended locally for some distance from the deepest points of the lake-basins along the floors of the principal Alpine river valleys.—On a shelly Boulder-clay in the so-called palagonite formation of Iceland, by Helgi **Pjetursson**. There is no equivalent in the Tertiary basalt plateaux of Britain of the great palagonite formation of Iceland. The basement layer of the breccia formation, resting directly upon the basalts, contains glaciated blocks of all sizes. These ground moraines are followed by tufaceous sandstones, conglomerate, columnar basalts, other ground moraines, and volcanic tuffs and breccias. At Birlandshöfdi a shelly Boulder-clay, 70 to 80 feet thick, rests upon the fundamental basalt, which here shows a glaciated surface. Unbroken shells are very rare. *Astarte borealis* is the most common shell, and *Saxicava arctica* and *Mya truncata* are less common, indicating that some of the older moraines are of Pleistocene age. The author concludes that volcanic activity did not pause in Iceland during the Glacial period, but that it was especially active at the beginning and the close of glaciation.

Anthropological Institute, May 5.—Mr. H. **Balfour**, the president, exhibited a stone celt, worn as an amulet, from Benin; some silver *ex voto* offerings from Malabar, and a dagger from Siam, on the sheath of which were natural markings, interpreted by the natives to represent the name of Allah.—Mr. A. L. **Lewis** read a paper on some stone circles in Derbyshire. Mr. Lewis first dealt with the Arborlow circle, which has recently been excavated by Mr. Gray under the auspices of the British Association. Like the Avebury circle, Arborlow is surrounded by an embankment outside a ditch, the latter, therefore, obviously not intended for defensive purposes. All the stones are now flat, with the exception of one which is leaning, and in consequence of this it is extremely difficult to fix the circumferential line or diameter. The general plan, however, is oval. Mr. Lewis was of opinion that in the centre there was a group of three upright stones opening to a point somewhat north of east, and facing probably to the Beltane sunrise. A skeleton—apparently a late interment—was found in the centre, but part of the embankment on the south-east has been formed into a tumulus, which was found to contain an interment of the Bronze age. Mr. Lewis was of opinion that sepulture was no part of the original purpose of the monument. Mr. Lewis also referred to other Derbyshire circles, including the "Wet Withins" and the "Nine Ladies." With regard to the latter, he was of opinion that the term "nine" as applied to standing stones simply meant "holy," and in support of this view he cited several instances of the sacred or mystic significance of the number.—Mr. **Lewis** also read a paper on some notes on orientation. He began by referring to the association—pointed out by Dr. Rivers—between south and right in Welsh and other languages, and considered that the reason was that, when the connection first arose, the people, for some ceremonial purpose, were accustomed to turn to the east on certain occasions, when their right sides would become their south sides, and he incidentally referred to the almost universal practice of church-goers of turning to the east at the recitation of the Creeds. He felt, therefore, that it was possible that the connection went no further back than the origin of this present-day custom, but still it might have originated in far remoter periods. The Greeks looked upon the right side as prosperous, while the Romans looked upon it as unlucky; but this was due to the fact that, while both peoples looked upon the north-east as the favourable quarter, the Greeks in their auguries turned to the north, while the Romans turned to the south. Mr. Lewis mentioned many instances showing how the north was looked upon as unlucky and the south as lucky, but this belief is by no means universal, and on the whole the north-east seems to be considered the most favourable quarter, and then the east. Summarising, Mr. Lewis was of opinion that on the whole the quarter from which the sunlight came was considered most favourable, and that the question of the favourableness of the right or left sides depended on the position taken up at the ceremonies. In conclusion, Mr. Lewis referred to a sort of symbolism of three and one which he had noticed in several stone circles. In a small circle in the Isle of Man there was a combination of one and three stones, but in many instances natural objects—especially the peaks of hills—have been used to suggest the symbolism. This is particularly noticeable at the circle at Penmaenmawr, where the Great Orme and two other hills make a trinity to the north-east, and at the circle on Bodmin Moor, where the three tips of Brown Willy are visible, due east of the circle, over a low intervening ridge.

Entomological Society, May 6.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. Willoughby **Gardner** exhibited nest cells of *Osmia xanthomelana* from Conway, North Wales. He said the species, one of our rarer mason bees, places its beautifully constructed pitcher-shaped cells at the roots of grass, usually four or five together. There is no previous record of the nest having been found since Mr. Waterhouse discovered and described it from Liverpool about sixty-five years ago.—Mr. M. **Jacoby** exhibited *Arsoa longimana*, Fairm., and *A. aranea*, from Madagascar, the only other specimens of these species he knew of being in the British Museum collection. He also exhibited *Megalopus melipona*, Bates, and *M. pilipes* from the Amazon, which bore a remarkable resemblance to a bee.—Mr. A. J. **Chitty** exhibited *Hydroporus bilineatus*, Sturm., a water-beetle new to Britain, discovered by Mr. Edward Waterhouse among some specimens of Hydroporus from Deal, given by Mr. Chitty to him as *H. granularis*. He also exhibited a specimen of the rare *Trechus rivularis* (*incilis* of Dawson), taken at Wicken Fen in August, 1900.—Mr. O. E. **Janson** exhibited specimens of *Neophaedimus melaleucus*, Fairm., a goliath beetle from Upper Tonkin, and remarked that the white colouring was derived from a dense clothing of peculiar semi-transparent coarse scales which were apparently easily removed by abrasion, and seemed to partake of the nature of the "fugitive" scales found upon freshly-emerged specimens of Hemaris and other Lepidoptera.—The president read a communication from Mr. G. F. **Leigh** on protective resemblance and other modes of defence adopted by the larvæ and pupæ of Natal Lepidoptera. He also exhibited the cocoons of *Eublemmistis chlorozonea* to illustrate the paper. Prof. Poulton also showed a specimen of *Polygonia C-album* in the attitude of prolonged repose, together with specimens of *Anaea moeris* set in different ways to illustrate its probable resting position. He said that probably the "C" or "comma" on the under surface of the hind-wings in butterflies belonging to the genus Polygonia (Grapta) represented in bright, strongly-reflecting "body-colour" the light shining through a semi-circular rent in a fragment of dead leaf.—Mr. G. A. J. Rothney communicated descriptions of twelve new genera and species of Ichneumonidæ, and three new species of Ampulex from India, by Peter **Cameron**.

Linnean Society, May 7.—Prof. S. H. Vines, F.R.S., president, in the chair.—The Ingolfiellidæ, fam. n.; a new type of Amphipoda, by Dr. H. J. **Hansen**. The greatest depth explored by the Danish *Ingolf* expedition in the summers of 1895 and 1896 was that of 1870 fathoms, a little south of the entrance to Davis Strait. A small quantity of bottom material showed several forms new to science, amongst which was a single specimen, having a likeness to the Caprellidæ, but with pleopods markedly differing from those of any known Amphipod. Some years later the

author examined a specimen of an allied species obtained by Dr. Th. Mortensen from an island in the Gulf of Siam. These two new species, *Ingolfiella abyssi* and *Ingolfiella littoralis*, one abyssal from the North Atlantic, the other from shallow water in the Pacific, agree in being extremely minute.—On the evolution of the Australian Marsupialia; with remarks on the relationships of the marsupials in general, by Mr. B. Arthur **Bensley**. The paper contains a minute description of the dentition of more than forty genera, and treats also of the structure of the hind foot. Mr. Bensley considers that the primary division of the Marsupialia should be based on the condition (syndactylous or eleutherodactylous) of the second and third digits of the hind foot, rather than on the condition (polyprotodont or diprotodont) of the incisor teeth; and he is disposed on this account to associate the Peramelidæ more closely with the Phalangeridæ than has hitherto been customary. The author regards the Australian marsupials as probably monophyletic, and considers, with Winge, that the ancestral forms were primitive members of the Didelphidæ, a family which must have had a wide geographical distribution in past times. A study of the dentition impels him to the conclusion that the primitive types were all insectivorous, but that the subsequent radiation, or divergent evolution, proceeded along two primary lines, one carnivorous, culminating in Sarcophilus, the other omnivorous and finally herbivorous. In the second line all of the advanced forms are diprotodont, and all of the typical terminal forms are highly specialised herbivora.—Copepoda Calanoida, chiefly abyssal, from the Faroe Channel and other parts of the North Atlantic, by Canon A. M. **Norman**, F.R.S. Most of the Copepoda mentioned were procured by Sir John Murray in the *Triton* expedition of 1882, at various depths to 600 fathoms; a few were from the *Valorous* expedition of 1875; the remainder from a gathering sent by Prof. Haddon from 200 fathoms forty miles N.N.W. of Achill Head. Some of the specimens have been examined and named by Prof. G. O. Sars, and the great interest of the observations now laid before the Society consists in the record of the geographical distribution of these small but ever active crustaceans. Thus, some of the Faroe Channel species found at considerable depths were taken by F. Nansen near the surface at the point reached by him nearest the Pole; the varying depths at which these organisms occur constitute isothermal lines, which largely determine their dispersion.

DUBLIN.

Royal Irish Academy, May 11.—Prof. Atkinson, president, in the chair.—Captain G. E. H. **Barrett-Hamilton** read an abstract of some results of his researches into the meaning of winter whitening in mammals and birds inhabiting snowy countries, and the occurrence of white markings in Vertebrates generally. He finds that the first-named colour-change is not a merely external factor having as its purpose the adaptation of the animal to its environment, but a peripheral atrophy symptomic of deep physiological changes occurring in species possessing a metabolism which varies with the season. Thus the white colour affects the different parts of the body in the same order as that in which subcutaneous fat is accumulated in the panniculus adiposus. The author further finds a connection between much of the permanently white parts of Vertebrates and the accumulation of subcutaneous fat. Such white colour is then due to peripheral atrophy. This atrophy may manifest itself either in deficiency of pigment or in complete absence of hair.—Captain **Barrett-Hamilton** also read a description of a remarkable addition to the list of British mammals of boreal type. This is a bank vole (Evotomys) inhabiting the small island of Skomer, off the coast of Pembrokeshire.—Mr. G. H. **Carpenter** read a paper on the relationships between the classes of the Arthropoda. In opposition to certain recent speculations as to the independent origin of insects, arachnids, and crustaceans from annelid worms, the author advocates a common Arthropod ancestry for the various classes. The conclusion drawn from the numerical agreement in segmentation between typical members of the three great Arthropod classes is that the ancestral arthropods possessed such a definite and limited number of segments, and that those groups with a large number of segments, such as most centipedes and millipedes, and many branchiopoda and trilobites, represent abnormal developments.

PARIS.

Academy of Sciences, May 25.—M. Albert Gaudry in the chair.—The action of acetylene upon cæsium-ammonium and rubidium-ammonium. The preparation and properties of the acetylenic acetylides $C_2.Cs_2,C_2H_2$, $C_2Rb_2.C_2H_2$, and the carbides of cæsium and rubidium, by M. Henri **Moissan**. By the action of acetylene upon solutions of cæsium and rubidium-ammonium compounds of the type C_2R_2,C_2H_2 are formed, from which the carbides C_2R_2 can be obtained by heating *in vacuo*. These carbides react with water, giving the alkali and pure acetylene; they are extremely energetic reducing agents, acting upon the peroxides of lead and manganese with explosive violence.—The influence exerted on the rotatory power of cyclic molecules by the introduction of double linkages into the nuclei containing the asymmetric carbon atom, by M. A. **Haller**. The condensation products obtained by acting upon methylhexanone with aldehydes in presence of sodium methylate have been examined for their rotatory power. The effect of the double linkage is in every case to increase the rotation.—On new sources of radiations capable of traversing metals, wood and other substances, and on the new actions produced by these radiations, by M. R. **Blondlot**. By applying the method described in an earlier paper, using the electric spark as a detector, radiations similar to those detected in the light from an incandescent mantle have now been found to be emitted from an ordinary Argand burner, and from a sheet of incandescent silver. The effects are observed after the radiations have passed through 0·3 mm. of aluminium, black paper, &c., and in the case of the polished silver sheet are polarised, but the polarisation disappears when the silver is covered with lamp black. The name *n*-rays is suggested for these radiations. The *n*-rays are incapable of exciting phosphorescence in bodies which acquire this property under the action of light, but sulphide of calcium, already slightly phosphorescent, shows an increase in lustre when exposed to these rays.—M. Munier-Chalmas was elected a member in the section of mineralogy in the place of the late M. Hautefeuille.—On the development of a given function in series by means of Jacobi polynomials, by M. W. **Stekloff**.—On the integrability of a differential expression, by M. P. **Montel**.—On a theorem of Lejeune-Dirichlet, by M. A. **Pellet**.—On double cylindrical networks, by M. L. **Raffy**.—On the deformation of surfaces, by M. Maurice **Servant**.—The law of displacement of thermodynamic equilibrium, by M. E. **Ariès**.—On the simultaneous variation of solar spots and terrestrial temperatures, by M. Alfred **Angot**. If at any given station the mean annual temperatures, t, present a variation parallel to the number of sun-spots, r, the relation $t=t_0+ar$ will hold approximately, t_0 and a being constants characteristic of the station. This formula is applied to ten years' observations from Guadeloupe.—The thermal conductivity of crystallised bismuth, by M. F. Louis **Perrot**. The conductivity is greatest perpendicular to the axis, and in the direction of the line of easiest cleavage.—On Hertzian waves in wireless telegraphy, by M. G. **Ferrié**.—On the polarised light diffused by refraction, by M. A. **Lafay**.—On the combined hydrogen contained in reduced copper, by M. Anatole **Leduc**. Five litres of air passed over a column of red-hot copper, in such a manner as to ensure superficial oxidation along its whole length, still leaves a weighable amount of hydrogen in the copper.—On the decomposition of lithium carbonate by heat, by M. P. **Lebeau**. Dissociation of lithium carbonate commences at about 600°, the dissociation pressure increasing to 91 mm. at 1000° C., and approaching 300 mm. at 1200° C. An attempt to prepare lithium oxide by heating the carbonate in a vacuum at 1000° was unsuccessful, as the oxide is itself volatile at this temperature, in which respect lithia is sharply differentiated from the alkalies and alkaline earths.—The electrolysis of barium sulphide with a diaphragm, by MM. André **Brochet** and Georges **Ranson**. Polysulphides of barium are formed at the anode, and baryta at the kathode. The latter being placed in a porous pot, the baryta is obtained in a pure state.—On the mode of splitting up of mixed organo-magnesium compounds; the action of ethylene

oxide, by M. V. **Grignard.** The experiments of M. Blaise have been repeated under slightly different conditions, the ether being distilled off before water is added. Good yields of primary alcohols are thus obtained, ethyl magnesium bromide and ethylene oxide giving 62 per cent. of the theoretical yield of normal butyl alcohol.—On acetones containing acetylene linkages. A new synthesis of the pyrazols, by MM. Ch. **Moureu** and M. **Brachin.** Ketones of the type $R—C\equiv C—Co—R^1$, which can be prepared by the action of acid chlorides or anhydrides upon the sodium derivatives of substituted acetylenes, react with hydrazines to form pyrazols. The constitution of pyrazols prepared from unsymmetrical β-diketones can thus be fixed with certainty.—On some addition products of vinyl-acetic acid, by M. R. **Lespieau.**—The electrolytic separation of manganese and iron, of aluminium from iron or nickel, and of zinc from iron, by MM. **Hollard** and **Bertiaux.** The separations are simplified by the reduction of the iron to the ferrous state by means of sulphur dioxide before proceeding to the electrolysis.—On a reaction of methyl violet in presence of sulphurous acid, by M. H. **Causse.** —On the determination of the respiratory exchanges in aquatic media, by MM. J. P. **Bounhiol** and A. **Foix.** —The mandibular glands of the larvæ of the Lepidoptera, by M. L. **Bordas.**—On *Degeeria funebris*, a parasite of *Haltica ampelophaga*, by MM. C. **Vaney** and A. **Conte.**— On the browning of the vine, by MM. L. **Ravaz** and L. **Sicard.**—On the start of a lateral branch inserted on the axis after the division of the embryo, by M. P. **Ledoux.** —On the specialisation of parasitism in *Erysiphe graminis*, by M. Em. **Marchal.**—Sexuality in the genus Monascus, by M. P. A. **Dangeard.**—Contribution to the cytological study of chlorphyllian bodies containing metachromatic corpuscles, by M. Jules **Villard.**—On the presence of cadaverine in the products of the hydrolysis of muscle, by MM. A. **Etard** and A. **Vila.** Cadaverine was isolated in notable quantities from the products of the hydrolysis of muscle in a slightly decomposed state. The occurrence of considerable quantities of this alkaloid in slightly decomposed meat would appear to exclude the hypothesis of microbial formation.—The arrangement of the scales in *Mesosaurus tenuidens*, by M. Léon **Vaillant.**—Retinal inertia relating to the sense of form; its variation according to the criterium adopted. The formation of a wave of sensibility on the retina, by MM. André **Broca** and D. **Sulzer.**—The destruction of termites, by M. A. **Loir.** The ravages of these ants at Bulawayo were so great that special attempts were made to destroy them on the large scale. The use of gaseous sulphur dioxide proved very effectual.—On the artificial culture of the truffle, by M. Raphael **Dubois.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 4.

ROYAL INSTITUTION, at 5.—Electric Resonance and Wireless Telegraphy: Prof. J. A. Fleming, F.R.S.

CHEMICAL SOCIETY, at 8.—Imino-ethers corresponding to Ortho-substituted Benzenoid Amines: G. D. Lander and F. T. Jewson.—(1) Formation of an Anhydride of Camphoryloxime; (2) The Mutarotation of Glucose as influenced by Acids, Bases and Salts; (3) The Solubility of Dynamic Isomerides: T. M. Lowry.—(1) Isomeric Partially Racemic Salts containing Quinquevalent Nitrogen. Part X. The Four Isomeric Hydrindamine d-Chlorocamphorsulphonates $NR_1N_2H_3$; (2) Isomeric Compounds of the Type $NR_1R_2H_3$: F. S. Kipping.—The Hydrolysis of Ethyl Mandelate by the Fat Splitting Enzyme, Lipase: H. D. Dakin.

RÖNTGEN SOCIETY, at 8.30.—On the Electric Field surrounding the X-Ray Tube: Rev. P. Mulholland.

LINNEAN SOCIETY, at 8.—Anatomy and Development of *Comys infelix*, Embleton, a Hymenopterous Parasite of *Lecanium hemisphaericum*: Miss Alice L. Embleton.—Notes on the Transition of Opposite Leaves into the Alternate Arrangement; a New Factor in Morphologic Observation: Percy Groom.

FRIDAY, JUNE 5.

ROYAL INSTITUTION, at 9.—The New Star in Gemini: Prof. H. H. Turner, F.R.S.

PHYSICAL SOCIETY, at 5.—Special Meeting at University College.—Radio-active Processes: Prof. Rutherford.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of Lower Tweedside, with Special Reference to the Long Excursion: J. G. Goodchild.

SATURDAY, JUNE 6.

ROYAL INSTITUTION, at 3.—The "De Magnete" and its Author: Prof. S. P. Thompson, F.R.S.

MONDAY, JUNE 8.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Journeys in Mongolia: C. W. Campbell.

INSTITUTE OF ACTUARIES, at 5.—Annual General Meeting.

WEDNESDAY, JUNE 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The First Year's Work of the National Antarctic Expedition: The President.

THURSDAY, JUNE 11.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4.30.—*Probable papers*: The Bending of Electric Waves round a Conducting Obstacle; Amended Result: H. M. Macdonald, F.R.S.—On the Propagation of Tremors along the Surface of an Elastic Solid: Prof. H. Lamb, F.R.S.—The Diffusion of Salts in Aqueous Solutions: J. C. Graham.—On the Structure of Gold Leaf, and the Absorption Spectrum of Gold: Prof. J. W. Mallet, F.R.S.—On Reptilian Remains from the Trias of Elgin: G. A. Boulenger, F.R.S.—A Method for the Investigation of Fossils by Serial Sections: Prof. W. J. Sollas, F.R.S.—An Account of the Devonian Fish, *Palaeospondylus Gunni*, Traquair: Prof. W. J. Sollas, F.R.S., and Miss Igerna B. J. Sollas.—The Measurements of Tissue Fluid in Man; Preliminary Note: Dr. G. Oliver.

MATHEMATICAL SOCIETY, at 5.30.—Quaternions: Major P. A. MacMahon.—Automorphic Functions and the General Theory of Algebraic Curves: Mr. H. W. Richmond.—Jacobi's Construction for Quadric Surfaces: Prof. G. B. Mathews.

FRIDAY, JUNE 12.

PHYSICAL SOCIETY, at 5.—Some Experiments on Shadows in an Astigmatic Beam of Light: Prof. S. P. Thompson.—The Positive Ionisation produced by Hot Platinum in Air at Low Pressures: O. W. Richardson.—On a Method of Determining the Viscosity of Pitch-like Solids: Prof. F. T. Trouton and E. S. Andrews.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—A List of Species of Mollusca from South Africa, forming an Appendix to G. B. Sowerby's "Marine Shells of South Africa": E. A. Smith.—On a New Genus, Planorbia, Moore, from the Albert Edward and Albert Nyanzas: J. E. S. Moore.—Notes on Some Jurassic Shells from Borneo, including a New Species of Trigonia: R. Bullen Newton.—Description of *Marginella lateritia*, n.sp., from the Andaman Islands: J. C. Melvill and E. R. Sykes.—New Mollusca from New Zealand: Rev. W. H. Webster.

CONTENTS.

THURSDAY, JUNE 11, 1903.

DIFFERENTIAL EQUATIONS.

A Treatise on Differential Equations. By Prof. A. R. Forsyth, Sc.D., LL.D., Math.D., F.R.S. Pp. xvi + 511. Third Edition. (London: Macmillan and Co., Ltd., 1903.) Price 14*s*.

THE value of this useful text-book has been increased by the inclusion in the third edition of important additional matter.

The principal additions are an account of Runge's method for the approximate numerical solution of ordinary differential equations, of Frobenius's method for the integration of linear equations in series, and of Jacobi's theory of multipliers.

The chief modifications of the matter treated in the earlier editions occur in the treatment of Lagrange's linear partial differential equation of the first order, in the discussion of the condition of integrability of a total differential equation, and in the treatment of Riccati's equation.

Of the above-mentioned subjects the one of greatest theoretic interest is probably the treatment of Lagrange's equation, whilst the most useful is Frobenius's method of integrating linear equations in series.

The theoretic interest of the treatment of Lagrange's equation arises from the fact that until Goursat published his "Leçons sur l'Intégration des Équations aux dérivées partielles du premier ordre" in 1891, the widely used rule for the solution of Lagrange's equation had not received adequate demonstration.[1]

If $u = a$, $v = b$ furnish values of z in terms of x, v which satisfy the equation

$$P\partial z/\partial x + Q\partial z/\partial y = R,$$

where P, Q, R are any functions of x, y, z; and if $\psi(x, y, z) = 0$ be any other integral, then the condition $\frac{\partial[\psi, u, v]}{[x, y, z]} = 0$ must be satisfied, *not necessarily identically, but in virtue of the relation between x, y, z given by $\psi(x, y, z) = 0$.* It is only when the above condition is satisfied identically that ψ is a function of u, v. In this case ψ is certainly included in the general integral. But it is possible to take a case of the general integral, and put it into a form in which the Jacobian does not vanish identically; *e.g.* if $x\partial z/\partial x + y\partial z/\partial y = z$, we may take $u \equiv y/x$, $v \equiv x/z$, $\psi \equiv y/x - x/z$ and the Jacobian vanishes identically; but if we put $\psi \equiv yz - x^2$, then the Jacobian $= -2\psi/(xz^2)$, which vanishes only when the relation between the variables is such as to make $\psi = 0$. Finally, it is possible to have singular integrals, which cannot be expressed in the form of the general integral at all. In this case, let $u = a$, $v = b$ be two integrals, and let $f(x,y,z) = 0$ be any other integral, then by elimination of y, z express $f(x,y,z) = 0$ in the form $\phi(x, u, v) = 0$.[2]

Then if D denote partial differentiation when x, u, v are the independent variables, it can be shown that $PD\phi(x, u, v)/Dx$ must vanish, not identically, but in virtue of the relation between x, y, z given by $f(x, y, z) = 0$. Prof. Forsyth proves that if P, Q, R are regular for values of x, y, z in the vicinity of any point on the integral $f(x, y, z) = 0$, then this integral is included in the general integral. Taking as an example the equation

$$(1 + \sqrt{z - x - y})\, \partial z/\partial x + \partial z/\partial y = 2,$$

we may take

$$u \equiv 2y - z,\ v \equiv y + 2\sqrt{z - x - y};$$

and $z = x + y$ is an integral not included in the general integral. In this case

$$\phi(x, u, v) \equiv (1 - \sqrt{1 + v - u - x})^2,$$

and $PD\phi(x, u, v)/Dx = -\sqrt{z - x - y}$, which vanishes when $z = x + y$. In this case it is at once seen that the coefficient $P \equiv 1 + \sqrt{z - x - y}$ is not regular in the vicinity of points on the integral $z = x + y$.

A similar point, arising out of the conditional vanishing of a Jacobian, comes up in connection with Art. 12. It is there proved that an ordinary differential equation of the first order and degree, with coefficients which are one-valued functions of the variables, has only one independent primitive.

As soon as the reader reaches the subject of singular solutions, he is forced to ask himself why the reasoning in Art. 12 is inapplicable. He wishes to have an explanation of the fact that the many-valuedness of the coefficients causes the reasoning to fail.

Suppose the equation is $2dy/dx + x + \sqrt{x^2 + 4y} = 0$. Two primitives of this are $c^2 + cx - y = 0$ and $x^2 + 4y = 0$. Their Jacobian is $2(x + 2c)$, which does not vanish identically, but conditionally, viz., at the point of contact of the envelope $x^2 + 4y = 0$ by the complete primitive $c^2 + cx - y = 0$.

The method of Frobenius for integrating linear differential equations in series is explained on pp. 235–249, and is applied to the solution of Bessel's equation. It is of a more general character than the special method applied to the same equation in chapter v.; and it exhibits the connection between the two solutions found by it. The connection between the two solutions obtained in chapter v. is difficult to perceive; and Frobenius's method has the advantage both in directness and simplicity. It is a valuable addition to the book.

Runge's method for the numerical solution of differential equations has suffered somewhat in the compression which the author has found necessary. Nevertheless, one cannot help regretting the omission to state the geometrical meaning of the expressions employed, and the connection of the method with Simpson's rule for the approximate evaluation of an integral. The student will probably be greatly perplexed as to the origin of the various quantities introduced and used in the investigation.

There are several difficulties in the discussion of the differential equation which is satisfied by the hypergeometric series in chapter vi. Although the subject cannot be properly dealt with without assuming a knowledge of the theory of functions, which is not to be expected of the majority of the readers of the book, yet there are some very obvious difficulties which could be removed by short explanations.

G

[1] See Chrystal, *Transactions* of the Royal Society of Edinburgh, vol. xxxvi. part ii., p. 551 (1891).

[2] Or by eliminating z, x in the form $\psi(y, u, v) = 0$, or by eliminating x, y in the form $\chi(z, u, v) = 0$.

It is stated (Art. 122) that there is a linear relation between any three of the twenty-four integrals of the equation. The limitation that it is essential to consider only such groups of three integrals as have a common domain does not appear until we reach Art. 124, where it seems to contradict the statement in Art. 122.

The twenty-four integrals are divided into six groups of four each, and the members of each group of four are described as being equal. It should be pointed out that the members of each group of four fall into two pairs, that the members of one of these pairs are equivalent to one another, as they have the same domain; but they do not have the same domain as the members of the other pair (which are equivalent to one another). The four members of a group of four are equivalent to one another only in the domain common to them all. The integrals of one pair are to be regarded as continuations of the integrals of the other pair. From this it follows that in any linear relation between three of the integrals, it is not possible to replace any integral by another member of the group of four to which it belongs without examining whether the integrals appearing in the final relation have a common domain.

For example, relation No. (vi.), p. 219, viz.:—

$$Y_1 = M_5Y_5 + N_5Y_6$$

is intelligible if we take

$$Y_1 = F(\alpha, \beta, \gamma, x)$$

$$Y_5 = (1 - x)^{-\alpha} F\left(\alpha, \gamma - \beta, \alpha - \beta + 1, \frac{1}{1-x}\right)$$

$$Y_6 = (1 - x)^{-\beta} F\left(\beta, \gamma - \alpha, \beta - \alpha + 1, \frac{1}{1-x}\right)$$

because these integrals have a common domain. But it becomes meaningless if we replace

$$Y_5 \text{ by } x^{-\alpha} F\left(\alpha, \alpha - \gamma + 1, \alpha - \beta + 1, \frac{1}{x}\right),$$

which belongs to the same group of four integrals as that previously taken for Y_5; and if we replace

$$Y_6 \text{ by } x^{-\beta} F\left(\beta, \beta - \gamma + 1, \beta - \alpha + 1, \frac{1}{x}\right);$$

for Y_1, Y_5, Y_6 have now no common domain, except possibly points on the unit circle. This peculiarity had been noticed by Kummer in his memoir on the hypergeometric series. He held that even supposing we make the changes described above for Y_5 and Y_6, the equation should not be rejected as meaningless; for the two sides are now the expansions of the same function of x, one proceeding according to powers of x, and convergent inside the unit circle, the other proceeding according to powers of $\frac{1}{x}$ and convergent outside the unit circle; and he illustrated the subject by deducing from one side of one of the equations the expansion of tan x in powers of x, and from the other side of the equation its expansion in powers of $\frac{1}{x}$.

The whole subject received a thorough revision by Goursat (in the *Annales* de l'École Normale Supérieure, Sér. ii. t. x. 1881), who shows that in some cases the linear relations between the three integrals do not possess the same form throughout the whole of the plane of the complex variable. There still remains, however, for future researchers the discovery of an algebraic demonstration of such equations as the linear relation between

$$F(\alpha, \beta, \gamma, x), \; x^{1-\gamma} F(\alpha-\gamma+1, \beta-\gamma+1, 2-\gamma, x),$$

and

$$F(\alpha, \beta, \alpha+\beta-\gamma+1, 1-x),$$

series proceeding respectively according to integral powers of x, non-integral powers of x, and integral powers of $(1 - x)$, where, however, the last series cannot be expanded in integral powers of x.

The following details may be noticed:—

I. There is some obscurity in the explanation given in the note to Art. 25.[1]

If the system of curves $f(x, y, c) = 0$ have a node-locus let the node on the curve $f(x, y, a) = 0$ be given by $\xi = \phi(a)$, $\eta = \psi(a)$.

The node-locus will be found by eliminating a between the last two equations. The point to be explained is the reason for the appearance of this locus as a factor in the equation $\text{Disct}_c\ f(x, y, c) = 0$.

The coordinates of the node on the curve $f(x, y, a+\delta a) = 0$ may be called $\xi + \delta\xi$, $\eta + \delta\eta$. Then the following equations hold:—$f(\xi, \eta, a) = 0$, $\frac{\partial f}{\partial \xi} = 0$, $\frac{\partial f}{\partial \eta} = 0$; and the equations which can be obtained from them by changing ξ, η, a into $\xi + \delta\xi$, $\eta + \delta\eta$, $a + \delta a$ respectively. Of this last set of three only the first is required, viz. $f(\xi + \delta\xi, \eta + \delta\eta, a + \delta a) = 0$. Neglecting quantities of the second order, and using the preceding equations, it follows that $\frac{\partial f}{\partial a}\delta a = 0$. Hence the values $\xi = \phi(a)$, $\eta = \psi(a)$ satisfy $\frac{\partial f}{\partial a} = 0$, as well as $f = 0$, and therefore the node-locus is a factor of $\text{Disct}_c\ f(x, y, c) = 0$.

II. The properties of the Schwarzian derivative (Art. 62) may be thrown into a more symmetric form, viz:—

$$\{s, x\}(dx)^2 = -\{x, s\}(ds)^2$$

$$\{s, x\}(dx)^2 = \{s, y\}(dy)^2 + \{y, x\}(dx)^2$$

$$= \{s, y\}(dy)^2 + \{y, v\}(dv)^2 + \{v, x\}(dx)^2.$$

III. In Art. 192, the argument may be stated thus:—

It is given that

$$\frac{\partial\left[\frac{\partial F}{\partial \xi}, \frac{\partial F}{\partial \eta}\right]}{\partial[\xi, \eta]} = 0.$$

From this it follows that

$$\frac{\partial\left[\xi\frac{\partial F}{\partial \xi} + \eta\frac{\partial F}{\partial \eta} - F, \frac{\partial F}{\partial \xi}\right]}{\partial[\xi, \eta]} = 0.$$

Hence the equation of the tangent plane to the surface $z = F(x, y)$, viz. $z = x\frac{\partial F}{\partial \xi} + y\frac{\partial F}{\partial \eta} - \left(\xi\frac{\partial F}{\partial \xi} + \eta\frac{\partial F}{\partial \eta} - F\right)$ can, by putting $\frac{\partial F}{\partial \xi} = \lambda$, be expressed in the form $z = \lambda x + y\phi(\lambda) + \psi(\lambda)$, so that it is expressible in terms of a single arbitrary parameter λ. The quantities $\xi, \eta, \frac{\partial F}{\partial \xi}, \frac{\partial F}{\partial \eta}$ are not all functions of a single parameter.

IV. The solutions of Laplace's equation, which have

[1] The word "discriminant-equation" in the fourth line should be "differential equation."

been discovered since the second edition of this book was printed, and in which the author has himself borne an honourable part, are, if we except an example very near to the end of the book, not mentioned.

THE MAGNITUDE OF THE PROTEINIC MOLECULE.

Die Grösse des Eiweissmoleküls. By Dr. F. N. Schulz. Pp. viii+106. (Jena: Gustav Fischer, 1903.) Price 2.50 marks.

THIS work is the second part of the author's "Studien zur Chemie der Eiweissstoffe"; the first part is entitled "Die Krystallisation von Eiweissstoffen und ihre Bedeutung für die Eiweisschemie," and is also published by Gustav Fischer.

The book is composed of five chapters. The first deals with elementary composition as a measure of the magnitude of the proteïnic molecule, and fills twenty-four pages. In it the author discusses firstly the ash of proteïns. This he divides into essential and non-essential parts, without predicating chemical essentiality of the former. He concludes that the ash is of no value for the purpose under consideration. He deals next with the sulphur, and shows that it can be used to give minimal values. It is pointed out how the difference in the ease of its elimination affects the results, and the methods of its determination are discussed.

In the second chapter the products of substitution are considered. This chapter contains fifty-three pages. Of the natural bodies oxyhæmoglobin and caseïn are the only ones lending themselves to calculation. Consideration of artificial products yields no figures of value at present. The substances resulting from association of acids and bases with proteïns are not as yet available for purposes of calculation. The same may be said of those of metals with proteïns, with the possible exception of Harnack's copper-albuminates. The author points out, however, that these substances need closer study.

In connection with these bodies the author diverges into a consideration of certain properties of colloids, and indicates that associations of colloids may simulate chemical compounds. He states emphatically that use of such words as *combination* and *compound,* in the case of certain proteïns and proteïnic derivatives, may be unwarranted:—

"Eine Hauptaufgabe dieser Abhandlung war es gerade, dass gezeigt wird, dass bisher *keine zwingenden Gründe* vorliegen, um z. B. bei den Metallalbuminaten, oder später bei den Halogenalbuminaten, Verbindungen der Eiweissstoffe nach stöchiometrischen Gesetzen annehmen zu müssen."

The products of interaction of proteïns and halogens (especially iodine) are dealt with at some length. The absence of harmony in the results of different observers is shown, and the complexity of the process is pointed out. The conclusion is reached that these substances are not yet trustworthy for computational purposes.

The subject is regarded in the third chapter from the aspect of the products of hydrolysis, and it is found that no single compound is of use for the required calculation. The chapter contains nine pages

The fourth chapter, which consists of six pages, deals with physical methods, and chiefly with the cryoscopic one. The author has again to regard the results with suspicion, owing to the ash and the undefined nature of the substances. There is apparently an indication that the molecular masses of peptones, proteoses, and more complex proteïns stand to one another in a series of increasing magnitudes. The numbers attached to the two former classes may be of the right order; those connected with the latter are, however, valueless.

The final chapter, containing four pages, is devoted to conclusions. The author considers that the present state of the subject is very unsatisfactory, and that the molecular magnitudes of the more complex proteïns cannot be even given with approximate certainty. Selected minimal values, as those of Vaubel, lying for the more complex proteïns between 5000 and 15,000, can be made to give apparent harmony. But, if selection is not made, the result is very different.

The necessity of starting with crystalline bodies, and of improved methods is emphasised. The author also lays stress on the necessity of studying proteïns in their colloidal aspect, saying:—

"Ich bin der Meinung, dass eine gründliche Erforschung der colloidalen Eigenschaften der Eiweisskörper, das Räthsel der Eiweisschemie eher aufklären wird, als eine detaillirte Untersuchung der Krystallinischen Eiweissspaltungsproducte."

He adopts throughout a position of impartial criticism, which is eminently sound. The results hitherto obtained have for him no great positive value at present; this he attributes to insufficient precision in the modes of investigation, although admitting that the cause may be inherent in the proteïnic nature.

Some might urge that publication is in these conditions premature. But in the present state of proteïnic chemistry such a pamphlet as this, permeated with sane criticism, and summarising what is known in a clear and agreeable manner, can only be of value. The just appreciation of the extreme importance of a study of the colloidal nature of proteïns is a main feature of the work.

It is a regrettable fact that no index of subject-matter is appended, although there is one of authors, and a table of contents.

F. ESCOMBE.

PHYSIOLOGICAL REPORTS.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by Sir John Batty Tuke, M.D., and D. Noël Paton, M.D. Vol. viii. (Edinburgh: Oliver and Boyd, 1903.)

THIS volume represents the work done in the laboratory in 1900 and 1901, and though a year late in its appearance is none the less welcome for that. Apart from one paper on the pollution of the Tyne Estuary, it is devoted to pathology and physiology.

Throughout there are records of the energy and helpfulness of the superintendent, Dr. Noël Paton, and no less than one-third of the articles are by him, either alone or in conjunction with others. Indeed, his

interests are perhaps too multifarious, for one or two of his papers seem to have come into print before the observations they contain were ripe for publication.

Nothing, however, could be more elaborate or painstaking than the opening article, a study of the dietary of the labouring classes of Edinburgh, of which the expenses were partly defrayed by the progressive Town Council. The details were procured by a band of lady students, and are often amusing if not always essential. Thus we are glad to learn that a lady who dresses "in the Canongate fashion of a loose blouse" gets on well with her neighbours, but tragic possibilities follow on our introduction to the husband; "Mr. T. is not a teetotaler and he smokes."

The most interesting result of the study is the startling discovery that porridge is rapidly disappearing as a staple article of diet with these people. In fact, the investigation might have been entitled "A Plea for Porridge," for the authors rightly insist upon its economic value.

Of the other articles, the longest is a contribution to the histology and metabolism of the fœtus and placenta of the rabbit, by Dr. Chipman. With so difficult a subject, and so confused a terminology, the author's lucidity of style is very welcome, and the illustrative microphotographs, numbering no less than 186, are eloquent of his sincerity. He throws light on many controversial points, *e.g.* the manner of first contact of the embryonic and maternal tissues, the "unequivocal differentiation" of these two tissues, and the relations of placental and fœtal glycogen. It is a pity that he says nothing of the glycogen in the fœtal muscles, where it is said to exist sometimes to the extent of 40 per cent. of the dried tissue. There is much about the formation of "fibrinous tissue" from extravasations of blood, but he ligatured the vessels at the outset to ensure, as he explains, an injection of the placentæ, and we would suggest that these extravasations may have been, in part, an artefact.

Dr. Rainy's paper on the action of diphtheria toxin on nerve cells is so excellent, so far as it goes, that we look forward to a further instalment next year. He obtains very definite intracellular effects, and avoids error by a most thorough series of controls. Also he gives an admirable history of the subject.

There are many other minor articles of varying value. Dr. Carmichael, working at the infections of the gall-bladder, injected microorganisms into a mesenteric vein in five rabbits, and since he gets but one positive result, he concludes that infection can occur only by direct extension or by the cystic artery; of such factors as the virulence of the organism, the nature of the animal, and the condition of the gall-bladder he takes no account.

We are glad to see that Miss Huie is continuing her observations on the histology of cell-metabolism which she began so successfully in Oxford. Dr. Dunlop, in some observations on prison diets, confirms Atwater's finding that Voit's classical standard of diet is too low. Finally, we would mention a curious study by Dr. Berry in comparative morphology, in which he concludes that the vermiform appendix is not vestigial but the summation of a long development.

OUR BOOK SHELF.

An Elementary Treatise on the Mechanics of Machinery, with Special Reference to the Mechanics of the Steam Engine. By Joseph N. Le Conte. Pp. xi+311; with 15 plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 10s. 6d. net.

THE author states that this book is the outcome of a series of lectures given to engineering students in the University of California.

In an introductory chapter relating to uniplanar motion, some properties of instantaneous centres and centrodes are given, and methods are set out of determining relative velocities, both linear and angular.

The next part is devoted to machinery of transmission, comprising rigid and flexible couplings, friction gearing, belt and rope gearing, and toothed gearing, the shafts being parallel, intersecting, or crossing, respectively. This part also includes chapters on parallel motions and cams.

The author has a leaning towards analytical rather than graphical treatment, and prefers accurate and complete investigations to simplified approximations. This is apt to result in formulæ which convey little meaning, and which repel by their complexity, requiring the subject-matter to be of great importance to justify their use. Thus in the discussion on wheel teeth there is an investigation into the equation to the profile which shall correspond with any given curve of action; and formidable expressions are given for calculating the angles of action in cycloidal and involute teeth. We should like to have seen these supplemented by graphical methods, using tracing paper and a pricker, after Mr. Last, whereby wheel teeth can be set out with perfect accuracy, with the minimum of trouble, and in such a way as to bring very prominently into notice the nature of the action between a pair of teeth.

Part iii. deals with the steam engine, the first chapter relating to the kinetics of the "piston-crank chain." Accurate formulæ are established giving the position, velocity and acceleration of any point moving with the connecting rod referred to the crank position, from which are deduced the special values for the centre of mass, the crosshead and crank pin. Formulæ for angular motions of the connecting rod are also given. In this chapter the simple and gridiron slide valves are considered, and also the Meyer and Thompson gears, Zeuner's valve diagram being used along with the formulæ.

Chapter ii. of this part is taken up with the dynamics of the steam engine, and investigates piston and crank efforts, inertia effects, counterbalancing, and the actions of the fly-wheel and governor. The formulæ of the preceding chapter are used to calculate the force actions in a small horizontal engine due to acceleration of the connecting rod for a number of points in the cycle; these are tabulated, and the results plotted in plates at the end of the volume.

In the mechanics of the steam engine, the use of the Fourier development, with the conception of rotating vectors, is preferable to the method adopted by the author. The series converges so rapidly that it is seldom necessary to go beyond the second or octave term, and a very clear view is obtained of the secondary actions due to obliquities of the connecting and eccentric rods.

The principle of balancing the forces on the crankshaft of an engine, ignoring those on the frame, is novel, and leads to curious results in the case of the Southern Pacific locomotive selected by the author as an example.

The investigation of the action of fly-wheel governors seems very complete, and is worth study.

Elementary Chemistry. By R. H. Bradbury, A.M., Ph.D. Pp. xii+157. (New York: Appleton, 1903.)

THE volume, according to the author, is for beginners in secondary schools and colleges. Whether this implies any previous knowledge of chemistry on their part is not stated, but, to judge from the character of the contents, the book may be placed in the hands of any beginner. The author has evidently taken great pains to arrange his subject-matter, and to present it in a simple and logical form—not by any means an easy task—and the result is decidedly good.

It is always possible to find points in the arrangement of a text-book which do not accord entirely with one's own views. For example, the first chemical experiment which is described is the electrolysis of water to demonstrate its composition. It is difficult to present this process honestly to the beginner. The author does his best by stating that "it is impossible to explain the *rôle* of the sulphuric acid in an elementary work, further than to say that while it conducts the current it is found unaltered after the experiment, and only the water is decomposed." After all this is only dodging the difficulty, which might be so easily avoided by reserving the experiment for a later stage, when the author could take the reader into his confidence.

The author in his preface acknowledges his indebtedness to Bancroft's work on the phase rule and to the work of another modern writer on physical chemistry, but the elementary student will be relieved to find that no reference to the phase rule, and very little to "physical chemistry," is embodied in the text. Arrhenius's theory of electrolysis is, however, introduced, and there can be little objection to this, seeing that a student may just as well begin to exert his imagination on the atoms in solution as in the gaseous form. It is just as difficult to form a mental picture of charcoal as a constituent of carbon dioxide as of the ion CO_3. The only difference between the two conceptions is that one is a demonstrable fact and the other a very useful fiction.

An important feature of the book is the experimental part which is to be used as a laboratory guide, and contains a series of simple and useful experiments plentifully sprinkled with questions and notes of interrogation. The volume is, in reality, two distinct books with separate indexes. Might one suggest their future publication in separate parts; for not only is it difficult to remember that the index to the first part is in the middle of the volume, but as the second part is for use in the laboratory, the whole book, which looks very nice in its olive-green cover, is bound to suffer from the proximity of reagents?

The book is well illustrated, and is further embellished with the portraits of ten distinguished chemists, among whom Moissan has the place of honour in the frontispiece. J. B. C.

Hampshire Days. By W. H. Hudson. Pp. xvi+344; illustrated. (London: Longmans, Green and Co., 1903.) Price 10*s*. 6*d*.

THE author of "The Naturalist in La Plata" has found a thoroughly congenial subject in Gilbert White's country, and discourses, in the work before us, in a delightfully gossipy way of the scenery, people, birds, insects, and plants of one of the most beautiful of all English counties. As usual, Mr. Hudson introduces, when occasion arises, earnest trains of thought, which raise his work far above the average of writings of this nature.

The greater part of the contents of this volume, we are told in the preface, is new, although nearly the whole scope of the work is based on certain articles which have appeared in *Longman's Magazine*. Although devoted as a whole to Hampshire, the book, as might be expected, mentions many episodes which might perfectly well have happened in any other English county. Notable among these is the account of the manner in which a young cuckoo ejected the rightful occupant—a robin—of the nest in which the intruder was hatched, an action of which the author was fortunate enough to have been an eye-witness. Perhaps the most curious feature in this drama was the utter neglect of the ejected and dying robin by its parents. In another part of the same chapter the author directs attention to the prevalence of red in the coats of forest animals at the time that the autumn russet prevails in their surroundings. He has, however, omitted to mention that it is just before this season the red deer and the roe change their summer russet for their winter blue.

The account of Selborne itself is continued in the latter half of the book. Over the natural beauties of the village and its surroundings, the author, needless to say, waxes eloquent, although he is far from complimentary to the personal appearance of its inhabitants. After writing the sentence that "if you want to see, I will not say a handsome, nor a pretty, but a passably fresh and pleasant face among the cottagers, you must go out of Selborne to some neighbouring village to look for it," will the author, we wonder, venture to pay another visit? We cannot, perhaps, bestow greater praise on Mr. Hudson's "Hampshire" than by saying it is fully equal to the best of his earlier efforts. R. L.

Wörterbuch der philosophischen Grundbegriffe. Von Dr. Friedr. Kirchner. Vierte neubearbeitete Auflage von Dr. Michaëlis. Pp. vi+587. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1903.) Price 5.60 marks.

IT is always difficult to indicate exactly the value of a dictionary, and that difficulty is increased when for the vices of omission it pleads the virtues of brevity. A dictionary of philosophy is hardest of all to judge because of a certain inner conflict between the spirit of philosophy and the nature of dictionaries. If the publishers feel justified in saying that this book responds to a widely felt need, we must admit that a fourth edition seems good evidence. To judge from the book, that need is for brief epitomes of great doctrines and concise definitions of terms. Terms of art are a fit subject for the lexicographer, more especially such remnants of constructive ingenuity as "Häcceität," "Aseïtät," and the like. But philosophical concepts and theories are not so tractable; here brevity is an ambiguous virtue, and the more ambitious articles seem to be so planned as to have full significance only for the more advanced student who, on the other hand, would bring to the book all he found there. "Kantianismus," for example, occupies two-thirds of a page. Of "Hedonismus" in modern times we learn only that it is more modest than of yore; where the term explained is one in common use, the strictly philosophical significance is omitted; *e.g.* under "Liebe (ἔρως)," the Platonic and Neo-Platonic significance is unmentioned; the direction "Vgl. Dualismus" seems purely illusory. Biography does not come within the scope of this book, but the references are usually given with dates. At the end there is a "Zeittafel" which might well be useful. It seems a matter for regret that the terms of the "new psychology" have not been included; they might at least outrival "Buridans Esel" or "Krokodilschluss" as Grundbegriffe. Yet allowing for these limitations, the book is a praiseworthy effort; it is generally accurate, sensibly printed, and of a useful size. Such eccentricities as "Hutcheson 1609–1747" (p. 14) can be corrected by the reader from the "Zeittafel." The bibliography attempted in some articles is a good feature worthy of more development. G. S. B.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Psychophysical Interaction.

SINCE NATURE is read by many people beside physicists and mathematicians, it may be useful to state explicitly that a letter with a diagram, on p. 102, is erroneous and misleading.

For the same reason it may be desirable to remark distinctly, in opposition to a notion *apparently* suggested by several previous writers, that guidance or deflection of motion is not in the least contradictory of the principle of the conservation of momentum. For the rest, all the letters of importance which have recently appeared are in accordance with my views. OLIVER LODGE.

I HAVE followed with much interest the discussion opened in your columns by Sir Oliver Lodge's recent contention that mind directs but does not create energy. What is aimed at, as I understand it, by this distinction is the reconciliation of the activity and efficiency of mind with the mechanical laws of the conservation of energy and momentum. The distinction itself is, as is well known, as old as Descartes, being designed by him to meet the same problem as it presented itself to the thinkers of the seventeenth century. As is also well known, it was immediately disowned by his successors on the ground that guidance or direction of energy by the mind is an interference with the operation of material forces as the physicist is bound to conceive of them not less than the creation of it. Why is it more inconceivable that mind should alter energy or momentum than that it should interfere in any way whatever with the material world as a closed mechanical system? While to Sir Oliver Lodge it seems axiomatic that mind cannot produce energy, to others it has seemed equally axiomatic that it cannot resist or control it. It remains, therefore, for those who propose to revive the above distinction as a way of making the relation of mind to matter comprehensible to show by an analysis of the conception of control that the direction of physical energy by the mind is any more intelligible than its creation. Failing this, the problem they have sought to solve by means of this formula only returns in a deeper form. How is mental efficiency in any shape to be reconciled with fundamental mechanical principles? The purpose of this letter is to suggest a form of solution, somewhat different from that of Prof. Ward's in his "Naturalism and Agnosticism," which makes recourse to so ambiguous a distinction unnecessary.

Stated in its most general form, the problem is that of the operation of mind upon matter. Three answers have stood out owing to the authority of those who at different times have advocated them:—

(1) It has been held that mind and matter are each in its own sphere effectively operative, but that these spheres are wholly different. They never touch or intersect. Where there appears to be coincidence, as in knowledge or in the action of one upon the other, this is to be explained (if an explanation is insisted on) as the result of prearrangement. Except in the form of the working hypothesis of parallelism, no responsible thinker would probably accept this "dualistic" theory at the present time, and it need not further be considered.

(2) The second answer is that which explains mental activity as merely apparent. The really active forces are material. Consciousness is merely a by-product, standing to material forces as the steam which is dissipated in the air stands to the steam-engine—a sign of its operation, but itself contributing nothing to its efficiency. This "materialistic" theory is surrounded by difficulties which this is not the place to discuss, but which the present generation seems to be in the main agreed are insuperable.

(3) A third view remains which takes up the problem at an earlier point, and asks whether our difficulty is not a self-made one. If we set out from the existence of mind and matter as two entirely separate substances, there is, it must be admitted, no way in which we can establish any continuity or causality between them. On the other hand, if we reverse this assumption, and regard the conception of two worlds, a physical and a mental, as one that grows up within (it is not said created by) our experience, a way seems opened up out of the difficulty. The conservation of energy and momentum, and the determination of their direction by physical antecedents, are from this point of view conceptions which are forced upon us in our endeavour to interpret to ourselves one side or aspect of our experience—that which we call the mechanical. Within the area so describable they are universal, ultimate, admitting of no exception. But the mechanical is only one side of our experience. Besides mechanical energy there is life. The phenomena of life violate no mechanical law, yet open up to us a new aspect of our world, a new form of "energy." We may, indeed, try to "explain" life as only a more complex mechanism, and this has been a common device since the time of Descartes. But the present day tendency to recognise here a *transitio in aliud genus*, and to reject (as leading to confusion) the attempt to explain the fuller, more concrete reality by formulæ applicable only to the more abstract, seems to be founded on a truer insight. What holds of the relation of life to mechanism holds also of the relation of mind to life in general. Here also a new world opens up with laws of its own, no more identifiable with those of matter or organism than the system of mechanical forces which make up the movement of the billiard ball upon the table or the contraction of the muscles in the player's arm is identifiable with his acquired dexterity or his gaming ambition.

"But how," it may be asked, "does all this help us? Granted the world of Nature has these different 'sides,' we are no nearer understanding how any one side is connected with another, least of all how the 'world as will and idea' is connected with the world as matter and energy." It is just here that I wish to invite the physicist who may not have considered the question in this light to make an experiment with his ideas which may not hitherto have suggested itself, and when suggested may appear to him as ridiculous as an invitation to vary his outlook upon the universe in the interest of science by standing upon his head. The suggestion is that instead of starting, as probably he has been accustomed to do, from the presupposition that the entirely real and concrete is what is known as the physical world, and that everything else must fall into line as in some sense a product or reflection of it, he should start from his own experience as a whole—his mind and will as it exercises itself in the world of reality in general, including, of course, other minds and wills—as though this were the primary, most entirely real and concrete fact that he knows, and regard all else as comparatively abstract and secondary. The former view I invite him to consider for the time being as analogous to the old Ptolemaic astronomy, the latter as the Copernican. When he has done so I ask him further to consider whether the operation of mind on matter need any longer constitute the insoluble problem the older hypothesis made of it. Putting aside the question of the relation of our individual minds to the mind of the Creator, the single "real" activity is from this point of view that of a conscious will in presence of a universe which it is its one supreme interest to understand and adapt to its own ends of life and well-being. The condition of such understanding and adaptation is selection and abstraction; its one supreme law *divide et impera*. A fundamental division at which developing experience early arrives is that of an inner and an outer—a self and other. A subdivision of the latter, which it is not long in achieving, is into the material other and the mental other—the physical and the social world. In this way the division proceeds, but always into parts of a whole of which we must keep a hold and to which we must ever return wherever the danger threatens of becoming the victim of our own abstractions. Treated as an articulate part of the whole, each field falls into its place in the organism of experience—general philosophy being the attempt to state what that place is; when hypostatised into an independent reality, still more when mistaken for the whole it leads only to confusion. From the beginning of speculation the front of the offending has here lain with Matter. Philo-

sophy from the time of Plato has had its own way of meeting it on its own ground, and disposing of its exclusive claims. I do not write here in the interests of transcendentalism, but merely to invite the attention of physicists to a point of view which students of modern psychology have borrowed from it, and are now generally seeking to apply to the problem of the relation between mental and physical energy. J. H. MUIRHEAD.

Birmingham, June 9.

Seismometry and Gëite.

HAD Dr. Chree (NATURE, May 21, p. 55) referred to the various papers about earthquakes in the reports of the British Association commencing in 1847 by William Hopkins, in the now somewhat antiquated *Transactions* of the Seismological Society of Japan, and in very many other publications relating to earthquakes, he would have seen that his instructive remarks relating to the propagation of waves in an isotropic medium were but repetitions of information with which seismologists have at least a slight acquaintance, whilst the suggestion that the velocities of such waves have been regarded as having a direct connection with Young's modulus is incorrect.

In connection with Bessemer steel, Young's modulus was mentioned, but I do not see that it was referred to repeatedly (NATURE, April 9, p. 538). In 1897 Dr. Chree made an attempt to calculate Young's modulus and the bulk modulus for the earth, but the grist he used was so doubtful in character that his results are not convincing. From some source or other he discovered that wave velocities of 12·5 and 2·5 km. per second had been determined, and these were assumed to be V_1 and V_2 for compressional and distortional waves passing *through* the world. One, if not both of these, are based upon *arcual* measurements; they are incorrect at that, and the latter seems more likely to represent the velocity of a surface undulation rather than a quantity corresponding to V_2.

What I pointed out was that recent determinations of a quantity probably corresponding to V_1 find a simple explanation by the assumption of a core that is fairly *homogeneous* and of fairly *definite dimensions*, which is not the solution of the seismological problems attempted by Dr. Chree. The reference to elastic moduli was incidental.

The chief objection raised to the iron core is not that iron, as we know it, will not convey vibrations at the observed speeds, but that if we take such a core, gravitational and astronomical requirements appear to be such that it must have dimensions which do not altogether accord with the interpretation given to seismometrical observations.

What Dr. Chree tells us about the possible relationship between seismic disturbances and the movements of magnetic needles is as well known to seismologists as what he has to say about wave velocities. Many of the chief magnetic observatories of the world have compared their magnetograms with long lists of world-shaking and other earthquakes, and the results are to be found in the British Association Reports, 1888 and 1889. From Dr. Chree's own comparisons at Kew (British Association Report, 1888, pp. 229 and 231, &c.), the movements he discovered were, with two possible exceptions, of "the ordinary magnetic small wave type," which "go on for hours if not for days." My conclusion is that at Kew, Greenwich, &c., needles seem not to be disturbed at the time of large earthquakes in the manner in which they are disturbed at Bombay and other places. At these latter places, where the movement of needles apparently accompanying the passage of the large waves indicates a possible magnetic disturbance directly due to seismic causes, the inference I made was that at such places H.F. and $(g-\gamma)$ may be abnormal. As an illustration of the coexistence of the *three* phenomena we may take the following:—

	H.F. (c.g.s.)	$(g-\gamma)$ cm.	Earthquake effect on magnetic needles
Kew	0·18451 (1901)	+ 40 (1900)	Undisturbed.
Batavia	0·36752 (1898)	+136 (1894)	Disturbed.

Whether these coincidences are accidental or general, observations are yet required. JOHN MILNE.

THE VITALITY OF THE TYPHOID BACILLUS.[1]

THE object of hygiene is to prevent disease. It is therefore necessary that the factors in the causation and dissemination of disease should be understood in order that adequate preventive measures may be adopted. The living agents responsible for the production of infectious diseases when they are discharged from affected individuals may find their way back to the human body by a number of indirect channels. The water, the soil, or the food may at times harbour and transmit the germs of disease. The conditions under which these morbid agents exist in the outside world constitute one of the most important subjects of hygienic inquiry. It cannot be said with regard to this phase in the life-history of pathogenic organisms that our knowledge is as accurate or extensive as it is in other directions. This is due to the difficulties that stand in the way of such investigations. The germs of disease undergo an enormous dilution in the air, water and soil, whilst they tend to become lost in the crowd of similar forms already existing in nature. The facts so far support the view that the parasitic microorganisms possess a considerable amount of resistance to external influences, and that the links which ensure their conservation and retransference to man are numerous and varied. A typical example is the bacillus of typhoid fever. This organism may become widely distributed through the dejecta. It may contaminate a water supply and directly, or by the agency of milk, produce a fresh outbreak of typhoid fever. It may infect the soil, and through it a number of raw vegetable foods. Its presence has been detected in the sewage-fed oyster, whilst tainted dust and flies aid in the distribution of the organism.

In studying the distribution of enteric fever, a physical factor which has to be considered is the influence of cold on the vitality of the specific organism. The effect of low temperatures upon microorganisms generally has formed a subject of inquiry from time to time. The latest experimental work has conclusively shown that bacteria retain their vitality under the most adverse conditions of cold that it is possible to devise. Prof. Sedgwick and Mr. Winslow, approaching the subject from the hygienic point of view, have carefully studied the influence of natural and normal conditions of cold upon the typhoid bacillus in particular. Their experiments were carried out with special reference to the danger of conveyance of the disease in question by polluted ice, and with reference to the seasonal distribution of the disease. The matter was undoubtedly one that called for investigation, and notably in a country where ice and iced drinks are in such universal demand. The authors were unable to find any recorded evidence of a conclusive character as to the spread of typhoid fever by a polluted ice supply, although it has been a common opinion that ice might be an important source of infection for typhoid fever and other intestinal diseases.

The apparent purity of ice is deceptive. It is true that water in freezing undergoes a certain amount of purification. It loses, on conversion into ice, saline constituents, contained air, and a certain proportion of organic suspended matter. At the same time, it is not entirely freed from microbes. The figures quoted by Prof. Sedgwick and Mr. Winslow show that snow-ice may contain an average of more than 600 bacteria per cub. cm. Figures are also given to indicate the enor-

[1] Experiments on the Effect of Freezing and other Low Temperatures upon the Viability of the Bacillus of Typhoid Fever, with Considerations regarding Ice as a Vehicle of Infectious Disease" By William T. Sedgwick, Ph.D., Professor of Biology, and Charles-Edward A. Winslow, S.M. Instructor in Biology in the Massachusetts Institute of Technology (*Memoirs* of the American Academy of Arts and Sciences, vol. xii. No. 5, 1902.)

mous number of bacteria present at times in ice-creams—one of the highest records being seven millions in one cub. cm. The sources of danger in ice-creams are obvious, as they come from the spoons and vessels, and the persons and dwellings of the street vendors.

Laboratory experiments have confirmed the conclusion that a freezing process is not necessarily fatal to bacterial life. We have instances of bacteria multiplying at zero, and of their survival after a six months' exposure to the temperature of liquid air. It is not therefore surprising that the American observers were unable to secure a complete sterilisation of bacterial cultures by the freezing methods they employed. The question became therefore a relative one. What was the probability or likelihood of infection through ice in the case of typhoid fever? It would appear that about 90 per cent. of the ordinary water bacteria are eliminated by the process of freezing. The authors find that, in the case of a specific pathogenic organism such as the *Bacillus typhosus,* less than one per cent. survive simple freezing for a period of fourteen days. Complete sterility did not occur even at the end of three months, whilst a process of alternate thawing and freezing, if on the whole more fatal to the typhoid germs than a simple freezing, was equally unsuccessful in effecting an absolute sterilisation of the infected water. The reduction in the number of typhoid bacilli in chilled water was approximately as great as occurred in ice. The process of destruction proved to be a continuous one, whether it occurred above or below the freezing-point, and whether the experiments were made in water or in soil. A progressive reduction in the number of organisms occurred to the extent of about 99 per cent., and proceeded *pari passu* with the duration of the experiment. Cold exercises a disinfecting action as regards the typhoid bacillus, and in natural ice there is a supplementary purifying influence to be taken into account, as, at the time of freezing, 90 per cent. of the germs are thrown out by a process of physical exclusion. These are the main conclusions arrived at, and the authors find that they are in accord with the general result of experience, namely, that natural ice can very rarely be a vehicle of typhoid fever.

The research may perhaps fairly be described as a study of the death-rate of typhoid bacilli under adverse conditions, as furnished by cold. The percentage mortality, as a matter of fact, is such as might occur under the influence of light, a poor food supply, and disinfectant agents generally. It is therefore permissible to think that the danger of infection in the case of ice, if it is minimised, is not by any means abolished. A certain number of typhoid bacilli, as the experiments show, do remain alive, and these may, on rethawing, undergo a rapid multiplication outside as well as inside the human body. And it has likewise to be remembered that it is notoriously difficult to trace the exact channels of infection in sporadic cases of typhoid fever. The infection has at times occurred from the most unexpected quarters.

Prof. Sedgwick and Mr. Winslow have rightly drawn attention to the unfavourable conditions furnished by natural ice for the propagation of the typhoid organism. It is at the same time feasible to assume that ice may likewise act as a conserving agent, inasmuch as the cold, whilst inhibiting the growth of the typhoid bacillus, will equally prevent the multiplication of other competitive forms of life.

The experiments do not affect the general question of the persistence of life at low temperatures. If the temperature be sufficiently low to produce a complete anæsthesia of the cells, cold tends to act as a conserving agent on the typhoid bacillus and allied forms.

It only remains to commend the memoir of Prof. Sedgwick and Mr. Winslow to the attention of all who are interested in the epidemiological questions involved.

ALLAN MACFADYEN.

NOTE ON THE PROBABLE OCCASIONAL INSTABILITY OF ALL MATTER.

As a summary of my remarks at the discussion on Prof. Rutherford's most interesting communication on the subject of radio-activity to the Physical Society of London on Friday last, June 5, I beg to communicate the following:—

Consider an electron or other particle, of mass m and of negative charge e, revolving at speed u round the much more massive rest of an atom possessing an equal positive charge. The centripetal force between them is

$$\frac{mu^2}{r} = \frac{e^2}{\mathrm{K}r^2},$$

where the first r strictly is measured to the centre of gravity of the two bodies, and the second r is the distance between their centres; but taking these as usual practically equal for the lighter body, we get Kepler's law for the case

$$ru^2 = \text{const.} = \frac{e^2}{\mathrm{K}m} \qquad (1)$$

Larmor has shown ("Æther and Matter," p. 227) that an electric charge subject to acceleration radiates some of its kinetic energy, though the radiation becomes of prominent amount only when the acceleration is great; as, for instance, when kathode rays are suddenly stopped by a target. The "power" of the radiation, or the energy lost per unit time, is

$$\mathrm{R} = \frac{2\mu e^2\dot{u}^2}{3v} \qquad (2)$$

where $\dot{u}$ is the acceleration of the electric charge e, and v is the velocity of light.

In the case of steady circular motion, the only acceleration is normal or centripetal, viz.

$$\dot{u} = u^2/r \qquad (3)$$

but that is just as effective for radiation purposes as the tangential variety.

Hence, combining the three equations, we get, for the radiating power,

$$\mathrm{R} = \frac{2}{3\mu} \cdot \left(\frac{m}{e}\right)^2 \cdot \frac{u^8}{v^5} \qquad (4)$$

that is, a constant multiplied by the eighth power of the velocity of the rapidly moving particle: an expression which corresponds with what for ordinary molecular motions is known as Stefan's law, connecting radiation with temperature, *i.e.* with square of molecular velocity.

Now the radiation loss is equivalent to a resisting medium, and accordingly the revolving particle tends to move inwards towards its centre, and its speed to increase in accordance with equation (1). A slight increase in speed brings about a great increase in radiating power, as is shown by equation (4); wherefore the change, once appreciably begun, may be expected to go on rapidly, until presently the speed approaches the velocity of light. On the electric theory of matter, radiation or loss of energy must occur from every atom, and therefore it is only a question of time how long an atom shall last before it reaches this stage.

Directly this stage is reached another effect supervenes; the rapidly moving portion of the mass begins rapidly to rise in value, according to a complicated expression not yet quite fully worked out. This effect

is unimportant until the speed comes very near to the light velocity, but the mass becomes suddenly infinite or very great when the light velocity is attained.

I find it difficult to realise the full effect of this kind of increase of mass, that is to say, of mass intrinsically possessed by the moving body, and not accreted on it from outside stationary matter. The latter effect is familiar in raindrops and in viscosity of gases, and it tends to reduce relative motion; but no previous instance is known where the mass of the moving body rises because it is itself a function of velocity. It would seem that the momentum must increase, and must disturb the balance of forces holding the parts of the system together. In an extreme case it might happen that the lighter body would suddenly become the heavier, would behave as if it had encountered an obstacle, and would jerk the rest of the atom off; or, on the other hand, it might happen that the most rapidly moving portion itself, by reason of its sudden access of momentum, would break loose and proceed tangentially. In any case it appears likely that an atom at this stage would begin to break up, as observed experimentally by Rutherford and Soddy; in other words, the fact of electronic radiation seems to carry with it the liability to change or decay of all matter possessing an electric constitution; the change from one form to another being accompanied, as they demonstrate in many cases, by radio-activity—a phenomenon which Strutt finds widely diffused.

It is hardly necessary to direct attention to a sort of astronomical analogy to this, though governed by different forces, in the contracting or gradual collapsing of a nebula, with the occasional shrinking off of peripheral material as an unstable stage is periodically reached, in accordance with the rough approximation known as Bode's law, together with the strong radio-activity of the central mass, and the conversion of constitutional potential energy into heat.

A few more words on the increase of mass at the critical velocity:—The only expression for mass as depending on velocity which has met with any attempt at experimental verification, is the expression of Abraham supposed to be verified by Kaufmann by direct experiment on curvature of kathode rays. Taking this as a simple example of the kind of effect to be expected, viz.

$$\frac{m}{m_0} = \frac{3}{4\beta^2}\left(\frac{1+\beta^2}{2\beta}\log\frac{1+\beta}{1-\beta} - 1\right) \quad . \quad . \quad . \quad . \quad (5)$$

where β is the ratio u/v, the speed of an electric particle to that of light, and m_0 its ordinary purely electric mass for slow motions, we find that when an electron is moving with *half* the speed of light, its mass is only 1.12 times what it was when stationary. At *three-quarters* of the speed of light the mass ratio becomes 1.37, or little more than a third greater than its normal value. At *nine-tenths* of the light velocity the mass is still not doubled, being only 1.8 times m_0.

When within 1 per cent. of the light speed the mass is trebled, or, more exactly, multiplied by 3.28, and when within one part in a thousand of its limiting velocity, the mass is almost exactly quintupled.

For higher speeds, say within $1/n$th of the speed of light, or $u=(1-1/n)v$, n being great, the expression for the electric mass ratio simplifies to

$$m = \frac{3}{4}\left\{\log(2n-1) - 1\right\}m_0 \quad . \quad . \quad . \quad . \quad (6)$$

which ultimately is truly infinite, but for even excessive values of n is only moderately great.

It is notable how close to the velocity of light it is necessary to get before this effect becomes prominent; the instability must be expected to arrive sharply whenever the velocity of light is from any cause, *e.g.* perturbation or collision, attained by any moving electrically charged part of an atom. Assuming a Maxwell distribution of velocities and an average speed, for the internal atomic motions, it may be possible (as J. J. Thomson suggested in NATURE of April 30, p. 601) to calculate what percentage of a given number of atoms reach the unstable stage by this means, and so to make a theoretical estimate of the amount of radio-activity to be expected, and of the life of an atom. But the slight constant radiation-loss seems competent to bring about instability and decay irrespective of collisions, and therefore independently of any Maxwell-Boltzmann law.

OLIVER J. LODGE.

PHOTOGRAPHS OF SNOW CRYSTALS.

At the beginning of last year (vol. lxv. p. 234) we summarised a paper contributed by Mr. W. A. Bentley to the U.S. *Monthly Weather Review* upon his photomicrographs of snow crystals. Mr. Bentley has made a study of the forms of snow crystals for more than twenty years, and has obtained a most valuable collection of photomicrographs taken with the object of discovering the connection between characteristic forms and particular meteorological conditions. During the winter of 1901–1902 a systematic record was secured by Mr. Bentley of a number of snow storms, and several good photomicrographs from each storm were obtained by him, more than two hundred pictures being added to his collection. The annual summary of the *Monthly Weather Review* for 1902 (vol. xxx. No. 13), which has just been received, contains reproductions of these photomicrographs and a paper by Mr. Bentley describing the various types of structure and the meteorological conditions prevailing at the time when they were produced. The paper contains an instructive account of snow crystals, and an analysis of the results of the studies carried on during the winter of 1901–1902. The interest of the pictures lies not merely in the fact that many of the forms photographed are very remarkable, but that they also represent, so far as possible, stages in the life-history of snowstorms, several pictures having been obtained of each storm, while at the same time a record was kept of the conditions of temperature, pressure, wind, cloud and position of storm from which the snow fell.

We print a few extracts from the contribution and reproduce several photomicrographs of exceptional interest from those given in the *Monthly Weather Review*.

In general the data tend to confirm further the conclusions of all observers, that a more or less intimate connection exists between form and size of nuclei, and the altitude and temperature of the air in which the crystals form. There can be no longer any doubt that there is a general law of distribution of the various types of crystals throughout the different portions of a great storm. On this point the data secured, both by direct observation and by a study of the weather maps, are much more complete and satisfactory than has hitherto been published. This aspect of our study received special consideration, because it was thought to be most important.

Snowstorms often cover a region of vast extent; crystallisation is going on within them over nearly the whole area, and therefore in regions that differ greatly among themselves as to temperature, humidity, air density, electrical conditions, &c. Moreover, the kind, number, dimensions, altitude and density of the clouds within those various regions differ so greatly one from another that the snow crystals emanating from each region furnish us rare opportunities for observing and studying the effects of each of these various conditions upon the forms.

The results arrived at by a study of the data secured during the four winters of 1898–99 to 1901–2, inclusive, in regard to the relative frequency of occurrences of the various types and the apparent connection between size and form and the air temperatures, agree in general with the results arrived at by many other meteorologists and observers, both in Europe and America, as set forth in the work "Schneekrystalle," by Dr. G. Hellmann, Berlin, 1893.

Doubtless the actual connection between forms and sizes of snow crystals and the temperature and density of the air is much more intimate than our present knowledge would indicate, because our studies are based on air temperatures at the earth's surface, instead of in the cloud strata where the snow crystals form. The temperature may often be mild at the earth's surface when the crystals are developing at high altitudes where the cold is intense, and such crystals should be classed with those deposited during extreme cold.

Structure of Snow Crystals.—The beautiful details, the lines, rods, flowery geometrical tracings and delicate symmetrically arranged shadings to be found within the interior portions of most of the more compact tabular crystals, and

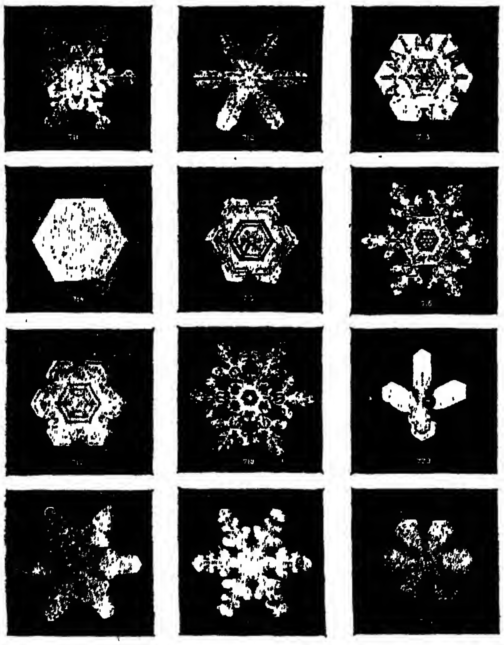

FIG. 1.—Nos. 711–724.

in less degree within the more open ones, have attracted the attention of nearly all observers who have studied snow crystals. That these interior details more or less perfectly outline preexisting forms must have been early recognised, yet the knowledge as to what they actually were remained long in obscurity, and a complete explanation of all of them is yet to be found. The investigations of Drs. Nordenskiold and G. Hellmann enable us to form a general conception as to their true character. These observers discovered that many of the lines, rods, and other configurations within the crystals, that add so much to the beauty of the forms, and which are so plainly revealed in the photomicrographs, are due to minute inclusions of air. This included air prevents a complete joining of the water molecules; the walls of the resultant air tubes cause the absorption and refraction of a part of the rays of light entering the crystal; hence, those portions appear darker by transmitted light than do the other portions. The softer and broader interior shadings may perhaps also be due, in whole or part, to the same cause, but if so, the corresponding inclusions of air must necessarily be much more attenuated and more widely diffused than in the former cases. We can only conjecture as to the manner in which these minute air tubes and blisters are formed. It may well be that some of them are the result of a sudden and simultaneous rushing together of water molecules around the crystal from all sides. This might result in the formation of closely contiguous parallel ledges, or laterally projecting outgrowths that are separated from each other during the initial impact by a narrow groove, or air space, but are soon bridged over by subsequent growth. Similar contiguous parallel growths occur frequently around the angles of very short columnar forms, and lend plausibility to this theory. Air spaces also exist within columnar forms, as noted by Hellmann and Nordenskiold. They seem to occur within such forms as hollow cup-like extensions, projecting perpendicularly within them from each of the ends of the crystals.

Modifications of Forms of Snow Crystals.—By close study of the photomicrographs, we find that the most common form outlined within the nuclear portions of the crystals is a simple star of six rays, a solid hexagon, and a circle. The subsequent additions assume a bewildering variety of shapes, each of which usually differs widely from the one that preceded it, and from the primitive nuclear form at its centre. Bearing in mind, however, the tendency of the crystals evolved within the upper clouds toward solidity, and the tendency of those from the lower clouds to form more branching open crystals, our task of deciphering the

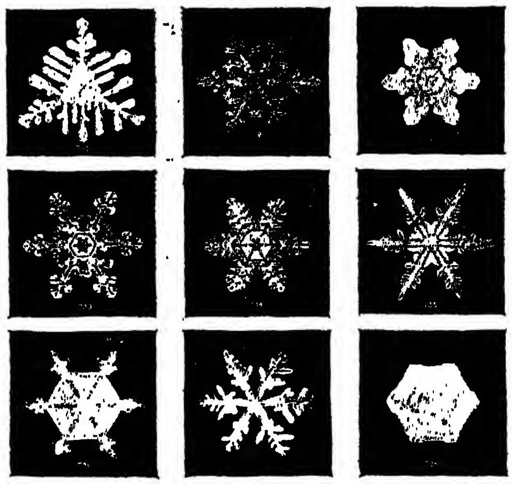

FIG. 2.—Nos. 730–738.

hieroglyphics, and of tracing thereby the probable flights of each individual crystal within the clouds, becomes much easier than might be anticipated.

Taking photomicrograph No. 821 as an example, we can picture with some certainty its various flights within the clouds during each stage of its growth. Star-shaped at birth, it was probably carried upward by ascending air currents, and at some upper level assumed the solid hexagonal form that we see outlined around the star-shaped nucleus. Having now become heavier, it probably descended, and acquired further growth at some lower level, such as that wherein it had its birth.

Modifications of Forms due to other Causes.—As it is generally conceded that winds play an important part in modifying the forms of snow crystals, let us consider the probable manner in which they operate to accomplish this.

Aside from causing modifications by wafting the crystals upward and downward within the clouds to regions varying in temperature, humidity, density, &c., as previously noted, the winds probably cause modifications in other ways. Violent winds may prevent a perfect and orderly joining of the aqueous molecules, causing imperfections in the forms, or perhaps amorphous, granular aggregations.

Again, they may waft greater quantities of water molecules to one or more portions of a growing crystal, causing abnormal growth to take place around such portions.

More important still, violent winds often cause fractures

to occur, especially as regards the branching forms, and whenever, as must often happen, subsequent growth takes place around and upon such broken crystals, irregular, unsymmetrical forms result. Doubtless, we may attribute the origin of some of the odd oblong crystals to the fact that crystallisation sometimes takes place around and upon a long broken branch, or other long portion detached by fracture from some preexisting crystal. Other odd forms seem to owe their abnormal character to design rather than accident. Columnar forms and, in a less degree, small solid tabular forms, being relatively so much heavier and more compact than stellar and similar branching forms, are much less likely than these to be wafted about and to receive modifications due to wind action.

Among the other causes of modification of forms, we must mention the close proximity of two or more crystals during one or more stages of their growth. This close proximity while developing would probably cause a greater growth of those portions of each contiguous crystal that lie farthest away from the crystal closely adjoining, and thus perfect symmetry would be impaired.

Considerable modifications of form are frequently due to the aggregation upon the crystals of amorphous or granular material, contributed by relatively coarse cloud spherules, particles of mist, or minute rain drops. Frail light, branching stellar and other forms are often rendered coarse and

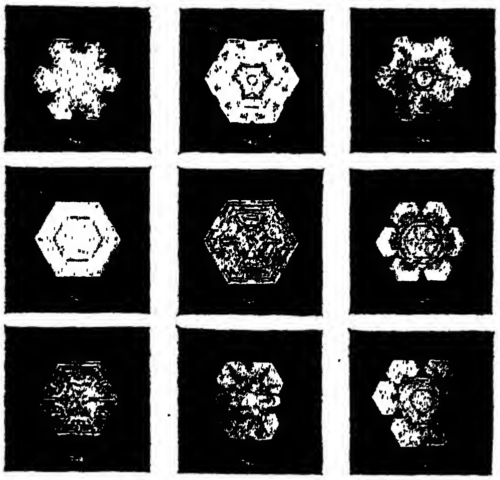

FIG. 3.—Nos. 742–750.

heavy by such additions taking place around and upon every angle of the crystals, so that they fall quickly to the earth.

Perfect crystals are frequently covered over and lines of beauty obliterated by such granular coatings. Granulation often proceeds to such a degree, and the true crystals are so deeply coated over and imbedded within it, that the character of the nucleus does not reveal itself, except under the closest examination. Such heavy granular covered crystals possess great interest for many reasons; they show when the character of the snow is due to the aggregation of relatively coarse cloud particles, or minute rain drops, and not to the aggregation of the much smaller molecules of water, presumably floating freely about between them. They also offer a complete explanation of the formation and growth of the very large rain drops that often fall from thunder-clouds and other rainstorms, if we accept the conclusion that such large drops result from the melting, or merging together, of one or more of the large granular crystals. For many reasons (among which we mention the almost invariable presence of low cloud strata when granulation occurs, and the aggregation occurring on perfect crystals, while these are presumably within the low clouds, rather than the occurrence of such aggregations as a distinct identity by itself) we are led to infer that, as a rule, the heavy granular covered crystals are peculiarly a product of the lower or intermediate cloud strata.

Chronological List of Snowstorms and Photomicrographs.—We now pass to the analysis of the photomicrographs of individual snow crystals secured during the remarkably

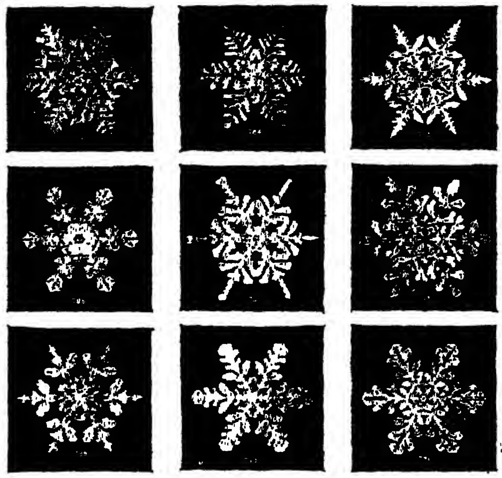

FIG. 4.—Nos. 783–791.

favourable winter of 1901–2. The number of individual crystals is very considerable, and the beautiful or odd and interesting ones form a large percentage of the whole number; many of them deserve special mention and prolonged close study. Considering them in chronological order, the snow forms of the blizzards of November, 1901, first demand our attention.

1901, *November* 26.—Eighteen different forms were photographed on this date, and among them two, Nos. 716 and 718 (Fig. 1), are very choice and beautiful. These exhibit a rather unusual and notable peculiarity, viz. a plain or delicately lined nucleus contrasted with a brecciated, boldly designed external portion; the latter approaching granulation, as though the nuclear portion was formed in clouds that were less dense and humid than those in which the outline portions were added. No. 712 is a fine example of the star-shaped form of crystal, exhibiting an extreme and slender development of the six primary rays without any corresponding development of the secondary rays. Many of the branching forms of this date were observed to be broken, as though by the action of violent winds.

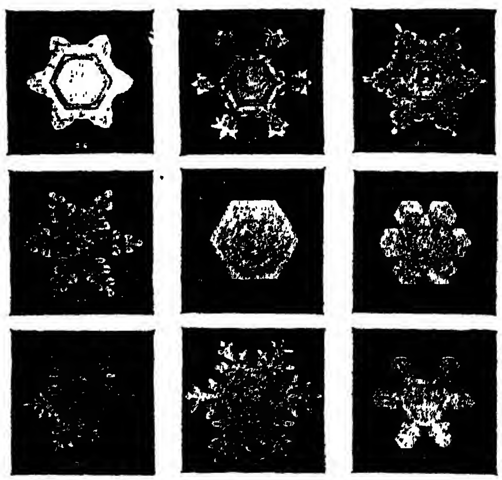

FIG 5—Nos. 816–824.

November 27.—Continuation of the same storm. Crystal types small, granular, and irregular, succeeded later by medium-sized, rather compact crystalline tabular forms and

a few doublets. Nos. 722 and 723 are charming patterns in snow architecture.

November 30.—Clouds rather thin stratus and nimbus. Crystal types wholly tabular of both open and stellate structure (Fig. 2, Nos. 730–737).

Among the seven forms of this date we find much to admire in the perfect beauty and symmetry of Nos. 731–734. The beautiful starfish design exhibited by No. 735 is somewhat rare. It is noteworthy that Prof. S. Squinabol, of the University of Padua, made drawings of a snow crystal found in Genoa in 1887 that closely resembles this latter one. The star with long slender rays deposited during this same storm, on November 26 (see No. 712), also closely resembles one figured by Squinabol in his work "La Navigata." No. 737 is another form that closely resembles some of those secured by other observers; it is very similar to some of the photomicrographs secured by Dr. Neuhaus, of Berlin, during the winter of 1893, and published in Dr. G. Hellmann's work.

December 4.—Clouds stratus, with detached running masses of low nimbus; probably high cirro-stratus above these. The western portion of this cold southern storm

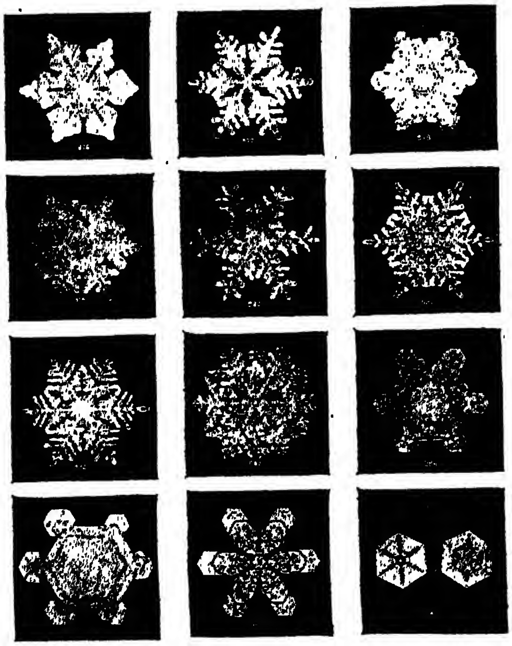

FIG. 6.—Nos. 876–888.

furnished a great number of forms of snow crystals that were in general rather small and compact.

The rare beauty of Nos. 745, 748 (Fig. 3) will appeal to all; crystallographers will find much of interest in No. 749.

1902, *January* 5.—The clouds of the western edge of the storm of January 5, 1902, furnished a large and splendid set of forms. Nos. 783, 785, 786, and 788 (Fig. 4) are exquisite examples of the frail, branching type of crystals. No. 785 is so rarely beautiful that Mr. Bentley describes it as the peer of any in his whole collection.

January 12.—Clouds obscured by heavy snowfall. A long series of magnificent snow crystals was secured from the clouds of the south-west-central portion of the storm or blizzard of January 12 (see Nos. 816–824, Fig. 5). The snow, as usual whenever it comes from the central-western portion of a storm, consisted of a great variety of types both columnar and tabular, but as the storm's central portion passed farther to the east, during the afternoon of January 12, the columnar forms ceased to be deposited. Nos. 818, 821 and 822 possess much beauty of design and perfection of form.

February 8.—Clouds stratus and nimbus; probably high cirro-stratus superimposed above them. A continuation of the storm of February 7, and its increase in rigour furnished more forms than were ever before secured by Mr. Bentley from any one storm. The beautiful branching crystals, Nos. 881 and 883 (Fig. 6), portray, in general, the characters of the forms that successively replaced both the solid tabular and columnar forms, as the western edge of the storm came nearer. No. 884 exhibits a most interesting phase of crystallic evolution; it is composed of four contiguous points, or rather portions, and two somewhat stunted portions, also similar to each other, but differing widely from the other four. No. 885 shows two overlapping additions to two of the points, thus rendering it of more than usual interest, and presenting us with another seemingly unsolvable problem in crystallography.

In concluding this mention of individual forms, it is worthy of note that, as during previous winters, occasionally single individual crystals, and more rarely larger numbers of such, produced during the storms of this winter, resembled closely, in outline or interior details, or oddity, one or more of the individual forms found among the snows of previous winters. The recurrence of similar types, after perhaps long intervals of time have elapsed, is a phenomenon of great interest.

In conclusion, it may be worth noting that by the addition of more than 200 plates during the past winter, the number of individual photomicrographs of crystals in Mr. Bentley's collection is brought up to somewhat more than 1000, no two of which are alike. This completes also his seventeenth year of photographic work among the snow crystals.

DR. A. A. COMMON, F.R.S.

IT was with deep regret that the news of the sudden death of Dr. Common had to be announced in the last number of this Journal. Dr. Common was so hale and hearty that it came as a great shock to his friends to find that he was no more, and his loss is felt not only by a great circle of friends, but by the astronomical world at large. Born in 1841, August 7, Dr. Andrew Ainslie Common was by profession an engineer, but quite at an early date he turned his attention to astronomy. In 1874 he became the possessor of a 5½-inch refractor, and three years later of an 18-inch reflector by Calver. It was evidently the use of the latter instrument which sowed the seed for his later important researches in the making and silvering of both large and small mirrors. An idea of his remarkable energy and success in the grinding and silvering of mirrors can be gathered from the following list of large reflectors in use which he referred to in his presidential address to Section A (Department of Astronomy) of the British Association in 1900. This list only referred to reflectors of 2ft. 6in. and upwards, and out of the nine given five were from his own workshop.

Reflectors of 2 ft. 6 in. and upwards.

	ft.	in.
Lord Rosse	6	0
Dr. Common	5	0
Melbourne	4	0
Paris	4	0
Meudon	3	3
Solar Physics Observatory (Common)	3	0
Crossley (Lick; Common)	3	0
Greenwich (Common)	2	6
Solar Physics Observatory (Common)	2	6

His knowledge of engineering was a valuable adjunct in the designing and construction of the mountings for his large mirrors. Dr. Common paid great attention to this latter question, for on it depended to a very great extent their efficiency and utilisation. He eliminated the "tube" by substituting a light framework of iron which reduced air currents to a minimum; adopted a new method to prevent the mirror being strained; mounted large mirrors equatorially by the ingenious device of reducing the friction of the moving parts by floating them in mercury; designed

and used successfully a slipping plate for use in the principal focus for photographic and visual purposes.

Not only was his time chiefly devoted to the construction of these astronomical instruments, but he turned them to great advantage by showing what could be done with them. Among the most noteworthy of these attainments was the magnificent photograph of the nebula of Orion which he secured in 1883, and for which he won the gold medal of the Royal Astronomical Society. Nebulæ, star clusters, &c., all came under his keen eye, and his researches not only demonstrated the cumulative effect of the photographic film, but showed that a new field of astronomical work was dawning by the employment of reflectors for long exposure photography.

More recently Dr. Common, among other things, turned his attention to the improvements in telescopic gun sights, and in this direction his loss will be keenly felt. He became a fellow of the Royal Astronomical Society in 1876, received the gold medal in 1884, and was president in 1895–96. He was elected a fellow of the Royal Society in 1885, and was an honorary LL.D. of St. Andrews.

Jovial, good-hearted, good-natured, and generous beyond degree in distributing his mirrors to those who would use them, all his friends join with the widow, son and three daughters whom he has left behind in mourning the loss of a personal friend.

WILLIAM J. S. LOCKYER.

PROF. C. A. BJERKNES.

IN NATURE of May 28 mention was made of the death of Prof. C. A. Bjerknes, of the University of Christiania, at the age of seventy-eight.

Though occupying the chair of pure mathematics, it was to applied mathematics, and especially to hydrodynamics, that Bjerknes devoted the greater part of his attention and study. He studied mathematics at the University of Göttingen early in the "fifties," his teachers including Riemann, who lectured on Abelian functions to a class of three only—Schering, Bjerknes and Dedekind—presumably between 1851, when Riemann obtained the doctorate, and 1859, when he was appointed ordinary professor, also Lejeune Dirichlet, who lectured to Schering and Bjerknes in 1855–56, and who proposed to them the problem of the ellipsoid in a steady fluid current. Solutions were given by both Schering and Bjerknes, but it was not until 1873 that Bjerknes completed his work on the problem of the general motion of an ellipsoid in fluid.

Bjerknes was at an early date attracted by the problem of replacing action at a distance by action of an intervening medium, and he exhibited considerable originality in the energy with which he took up the advancement of a doctrine which at that time received little support. The discovery that a sphere could move through a perfect liquid without retardation having shown that the existence of an ether does not involve a violation of Newton's first law, Bjerknes set to work to investigate the forces acting between two spheres moving in liquid, and in particular he developed the notion of "pulsating" spheres, *i.e.* spheres fluctuating periodically in volume, finding that between such spheres attractions and repulsions exist, obeying the law of the inverse square, and their sense being dependent on whether the phases are the same or opposite. The discussion of all the terms entering into the expressions for the forces was not completed until a comparatively late date, and in the meanwhile dynamical theories of physical phenomena have developed in other quarters, and ethers differing in their properties from ordinary matter, and in particular from matter in a fluid state, have come into existence. But another interest was aroused in these hydrodynamical attractions and repulsions by the experimental verifications of the results of the theory which were successfully carried out by both Prof. C. A. Bjerknes and his son, and of which we hope to give a fuller account shortly. These experiments were commenced in 1875, using rough and ready methods, but the apparatus have been gradually improved, and a number of papers on the subject were published, chiefly in the period 1878–1880, by Bjerknes and Schiötz in the Christiania *Forhandlinger*.

Among Bjerknes's other writings we note the biographical notice "Niels Henrik Abel; tableau de sa vie et de son action scientifique," published at Paris in 1885. Prof. V. Bjerknes has for many years collaborated with his father, and the second volume of his "Vorlesungen nach C. A. Bjerknes' Theorie" only appeared quite recently.

G. H. BRYAN.

NOTES.

MR. BALFOUR has accepted the presidency of the British Association for the meeting to be held at Cambridge in 1904.

PROF. RAY LANKESTER has been elected a Foreign Associate of the National Academy of Sciences, Washington, and a member of the American Philosophical Society, Philadelphia.

WE learn from the Paris correspondent of the *Times* that a monument, which has been erected by public subscription to the memory of Pasteur, was unveiled at Chartres on Sunday. This memorial specially commemorates the services of the great bacteriologist to agriculture by his discovery of a specific for anthrax, which resulted from a long series of experiments undertaken at a local farm. The principal feature of the monument is a high relief, which represents Pasteur and his assistants at work. It is the design of Dr. Paul Richer, who, besides being a member of the Academy of Medicine, is a distinguished sculptor.

A REUTER message from Simonstown, dated June 9, states that the German Antarctic ship *Gauss* arrived there on Tuesday morning after a successful year's work in the South Polar regions. She will remain there for three weeks to refit, and will then sail for home. On sailing from Cape Town the *Gauss* called at Kerguelen Island, and landed a party, which reached the floating ice on February 14, 1902. The ship was ice-bound on February 22 in lat. 66½, long. 90. New land was discovered, which was named the Emperor William II. Land. This was covered with ice, with the exception of an inactive volcano. The expedition was ice-bound here for almost a year, and many scientific investigations were carried out during this period. The ship left the ice on April 8 and proceeded to Durban, passing Kerguelen Island, and calling at St. Paul and New Amsterdam Islands. The members of the expedition enjoyed good health, there being no case of sickness, accident, or death during the whole cruise. Prof. Drygalski speaks in the highest terms of the vessel's behaviour, both in the sea and in the ice.

THE Hanbury gold medal has this year been awarded to M. Eugène Collin, École de Pharmacie, Paris.

A TABLET placed on the wall of Coate House, near Swindon, Wilts, the birthplace of Richard Jefferies, was unveiled by Prof. N. Story Maskelyne on June 6.

THE Vega medal of the Stockholm Society of Anthropology and Geography has been awarded to Prof. von Richthofen, of Berlin.

A NEW serum department of the Jenner Institute, at Elstree, will be opened on July 3. Dr. George Dean is the bacteriologist in charge of the department.

AN expedition in charge of Dr. F. A. Cook, of Brooklyn, is, says *Science*, to explore Mount McKinley and other Alaskan mountains under the auspices of the Geographical Society of Philadelphia and the Arctic Club, of New York.

THE Geological Society has made the first award of the proceeds of the Daniel Pidgeon fund, founded by Mrs. Pidgeon in accordance with the testamentary directions of her husband, the late Mr. Daniel Pidgeon, to Dr. E. W. Skeats, of the Royal College of Science.

THE Brussels *Bulletin Commercial* states that the Municipal Council of Lorient has recently decided to organise an International Exhibition of industry, agriculture, maritime defence, and fine arts, to be held from July to October of this year.

IT is reported that a young Austrian doctor named Sachs has fallen a victim to his scientific zeal, having accidentally inoculated himself with plague, from the effects of which he died after a short illness. Such regrettable incidents will occur while scientific research is pursued, and cannot be avoided even by the greatest foresight. There is no likelihood that other cases will develop, as under good hygienic conditions plague is not particularly infectious from man to man, and European doctors and nurses tending the sick seldom contract the disease.

THE wide distribution of typhoid-infected blankets that had been used in South Africa is another "regrettable incident" of the campaign, though those who made use of manifestly soiled blankets without washing them cannot be held blameless. On moist fabrics it has been proved that the typhoid bacillus retains its vitality for many weeks or even months.

Science announces that Prof. Florian Cajori, professor of mathematics at Colorado College, has been appointed representative of the United States on the international committee of the Congress for the Study of the History of the Sciences, which will make arrangements for the next meeting of the Congress at Berlin in 1906.

AT a meeting of the German Chemical Society on June 4 the presentation of the Hofmann foundation gold medal was made to Sir William Ramsay and to Prof. Moissan, of Paris. This medal is to be awarded once in every five years to a foreigner for distinguished chemical research work. The medal awarded to Sir William Ramsay bears on the obverse the effigy of Hofmann and on the reverse the inscription "For distinguished work in the field of general chemistry, and particularly for the discovery of new ingredients of the air."

BY the death of M. Eugène Demarcay at the early age of fifty-one, French science has suffered a severe loss. Although his earlier work was in the field of organic chemistry, his name is best known in connection with his researches on the chemistry of the rare earths. The magnificent specimens of pure salts of neodidymium, praseodidymium, samarium and europium shown by him at the Paris Exhibition of 1900 were the result of years of work of the most painstaking and laborious kind in a field in which he was one of the pioneers, and in which the number of workers is still too few.

AN Engineering Conference in connection with the Institution of Civil Engineers will commence on June 16 when Mr. W. H. Maw will deliver the eleventh "James Forrest" lecture on "Some Unsolved Problems in Engineering." On June 17 Mr. J. C. Hawkshaw, president, will inaugurate the conference with a short address to all the sections. The sections with their chairmen are as follows:—(1) Railways, Sir Guilford Molesworth, K.C.I.E.; (2) harbours, docks, and canals, Sir Leader Williams; (3) machinery, Dr. Alexander B. W. Kennedy, F.R.S.; (4) mining and metallurgy, Mr. E. P. Martin; (5) shipbuilding, Sir John I. Thornycroft, F.R.S.; (6) waterworks, sewerage, and gasworks, Sir Alexander Binnie; (7) applications of electricity, Mr. Alexander Siemens.

A PRACTICAL demonstration of the great power of the Marconi Wireless Telegraph station at Poldhu was given by Prof. Fleming during his lecture at the Royal Institution last week. A large mast had been erected above the Institution, and a complete receiving station set up; messages were received from Mr. Marconi, signalling from Poldhu, and also from a transmitting station at University College. All the experiments passed off without the slightest hitch. Prof. Fleming, in speaking of the future prospects of wireless telegraphy, laid stress upon the fact that there was a large sphere of usefulness open to it which submarine cables and land telegraphs could not touch.

IN the House of Commons on Monday Mr. Austen Chamberlain, speaking on the vote for the telegraph Services, referred at some length to the relations between the Post Office and the Marconi Wireless Telegraph Co. He said that the Post Office had no desire to check the progress of wireless telegraphy, nor could they have done so had they wished, as their monopoly did not extend beyond the three-mile limit. The Marconi Co. had, however, asked for too much; in the first instance they asked to be given a permanent and exclusive right to work wireless telegraphy in this country, which he could not grant, especially after the Post Office's experience with the telephone system. He had, however, granted them a private wire to Poldhu on the ordinary terms as soon as they asked for it, but before undertaking to act as their agents for the collection of messages, as was done for the cable companies, the Post Office required that certain conditions should be fulfilled in order to safeguard the Admiralty, and also asked that their experts should be satisfied that the company were able to carry on their business and transmit messages across the Atlantic commercially. He was still waiting an answer to this request, which was made last March. This statement does not quite tally with the accounts which were published last February, and were allowed then to pass uncontradicted. In any case there seems no reason why the Marconi Company should be required to pass an examination set by the Post Office; if people wish to risk sending messages by wireless telegraphy to America, they ought to be allowed full facilities for doing so; the Post Office by taking in the messages need incur no responsibility, by refusing to take them in it renders itself open to the charge of obstructing progress.

REUTER'S Agency is informed that a large number of foreign Government and technical delegates will be present

at the International Fire Prevention Congress which is to be held in London next month. The congress has been convened by the British Fire Prevention Committee, and will work in six sections, the papers and discussions being in English, French, and German.

WE regret to record the death, on May 30, of Mr. Alfred Haviland, aged seventy-eight. He had for many years devoted attention to the geographical distribution of disease in Great Britain, more especially of cancer and heart disease, having published maps and a separate volume on the subject.

WE learn from a cutting from the *Brisbane Courier* that Dr. J. P. Thomson, the hon. secretary of the Royal Geographical Society of Australasia, has left Brisbane on a visit to America, Great Britain and the Continent. At a meeting prior to his departure Dr. Thomson was invested with the powers of a delegate from the Australasian Society to all kindred societies in the various centres he may visit.

THE death is announced of Prof. Deichmüller, extraordinary professor of astronomy at Bonn University. From the *Athenaeum* we learn that he was born on February 25, 1855, and not long after completing his nineteenth year took part in the German expedition to observe the transit of Venus at Tschifu in 1874. Ever since October, 1876, he had been attached to the Bonn Observatory, and had shown skill not only as an astronomical observer and calculator, but also as a mechanician. He took a prominent part in the teaching at the University, and was made extraordinary professor of astronomy in 1897.

AN account of the life and works of the late Prof. Willard Gibbs is given in the Yale *Alumni Weekly* for May 6. It contains a portrait of Prof. Gibbs, and a chronological record of his principal published papers, together with a list of some of his academic distinctions and of the societies of which he was a member. Besides the papers which have done most to make his name known, Prof. Gibbs made important contributions in the domain of physical optics, notably in connection with the electromagnetic theory, but it is only by an exhaustive study of the papers themselves that his work can be adequately appreciated.

M. DE FONVIELLE writes that at the end of April a balloon belonging to the German Aëronautical Society left Berlin in the morning and landed at Skjolkör, in Seeland, in the afternoon, having crossed the Baltic in nine hours. The balloon was subsequently destroyed by a spontaneous explosion, the result of an electric discharge. The balloon reached an altitude of 4000 metres, where a temperature of -16° C. was registered. During the descent of the balloon the aëronauts observed crystals of snow falling in the car; the electricity generated by the formation of the snow had not had time to escape before the first impact with the earth, because the descent was very rapid. When the pilot took hold of the valve line an explosion occurred and ignited the gas of the balloon.

WE have received an advance copy of Merck's annual report for 1902 on advancements in pharmaceutical chemistry and therapeutics. It is a valuable and interesting summary of new preparations introduced for the treatment of disease, and should be in the hands of every medical man. It contains, in addition, notes upon many old remedies and the manner of prescribing them, together with a full bibliography.

IT is announced that Dr. Louis Martin, of the Pasteur Institute, Paris, has succeeded in preparing pastilles of an anti-diphtheritic serum for local treatment. The serum is an anti-microbic one obtained by the injection of dead diphtheria bacilli. These pastilles will not replace the injection of the serum, but will supplement the action of the latter, and during convalescence will remove contagion by destroying the diphtheria bacilli in the patient's throat.

MR. JONATHAN HUTCHINSON, F.R.S., has returned from his tour in India and Ceylon more convinced than ever of the correctness of his theory that leprosy is connected with the consumption of fish. In a letter to the *Times* (May 25) he states that there is no risk whatever from fresh or well-cured fish; the danger comes when decomposition commences. He points out that there is an excessive prevalence of leprosy among the Roman Catholic community in India, and suggests that the fast-day ordinances should be modified, also that the salt-tax should be abolished. The leprosy bacillus has never been found in fish, and Mr. Hutchinson does not explain how it is that fish becomes infective when stale.

MR. DAVID HOUSTON has examined bacteriologically a number of samples of Irish butter publicly exhibited, and concludes that a bacteriological examination will yield important information concerning the grade of any particular sample of butter. For example, one prize butter contained 260 spores of moulds per gram; the creamery was visited and the walls were found to be covered with a growth of mould. Another creamery sent a "preserved" sample and gained a prize. A specimen of the butter-milk taken from the churn was found to be crowded with putrefying and gas-forming bacteria, together with wild yeasts and moulds; a most undesirable state of things, and revealing why a "preserved" sample was exhibited.

IT has been stated by some authorities that the colon bacillus is normally present in the digestive tract of oysters. As this bacillus is undesirable in water used for drinking purposes, inasmuch as its presence may indicate the pollution of such water with sewage, it is not surprising that considerable interest has been aroused by its being reputed to be constantly present in the bodies of these molluscs. Mr. Caleb A. Fuller, of the Brown University, U.S.A., has endeavoured to throw fresh light on the subject by carrying out a systematic qualitative bacteriological examination of the digestive tract in the case of more than 2000 oysters. The specimens were taken from a bank which was free from any trace of pollution, and the colon bacillus was entirely absent from the adjacent sea-water. Sixteen different varieties of bacteria were isolated and examined, but not a single colon bacillus was discovered. This result would seem to indicate that oysters do *not* normally contain the *B. coli communis*, and that if it is found in their digestive tract, suspicion should fall on the breeding ground as having been exposed to pollution.

THE report of the Fernley Observatory, Southport, for the year 1902, shows that the work of this well-equipped establishment has been kept up to the usual high standard of efficiency. Mr. Baxendell does excellent work, not only in taking observations, but by instituting useful comparisons between various instruments and methods. The delicate records of the Halliwell self-registering rain-gauge give much satisfaction; this instrument recorded 641 hours of rain against 573 hours by another recording gauge. The comparison of the Campbell-Stokes and Jordan sunshine records gave only a difference of fifteen hours in the year in favour of the latter instrument, a much closer result in tabulating the records than some less careful observers might have reached. Several new tables have been added,

dealing with hourly results; one of these shows that the land and sea breezes are unusually marked at Southport, to an extent, the author remarks, of which meteorologists were not aware. The report contains the usual interesting comparison of climatological statistics with other health resorts.

THE Meteorological Office pilot chart for June shows that, as a result of the decision of the shipping companies to divert temporarily the steamer routes to the southward, there has been a great decrease in the number of ice reports from the southern extremity of the Newfoundland Bank. With the opening of the St. Lawrence season, however, reports from the northern part of the Bank are becoming more frequent. Another feature of the chart is an illustrated description of the violent storm of wind, rain and snow which, originating near Corsica, suddenly developed great energy on the evening of April 16, and starting off across north Italy, travelled through Austria and Poland to the Baltic and the Gulf of Bothnia.

THE twenty-second number of the pamphlet series issued by the West Indian Department of Agriculture forms part ii. of Mr. Maxwell-Lefroy's investigation of "The Scale Insects of the Lesser Antilles." It contains fifty pages of valuable illustrated information on a subject which is of the greatest importance to the colonists, as scale insects are becoming increasingly troublesome in some of the islands. The twenty-third pamphlet contains Mr. John Barclay's "Notes on Poultry in the West Indies." Hitherto the only information which the colonists had on the subject of poultry applied to countries well outside the tropics, but Mr. Barclay, of the Jamaica Agricultural Society, has for several years past devoted personal attention to the rearing of poultry in a tropical climate.

COMMANDER WHITEHOUSE, R.N., has, we learn from the *Times*, returned to England on sick leave from the survey of the southern portion of the Victoria Nyanza. With the recently inaugurated service of steamers round the lake the quickest route to the Tanganyika region will be by way of the Uganda Railway, and a project is on foot for opening a route from Lake Victoria to the north of Tanganyika to connect with the steamer on the last-named lake. Discoveries of gold are stated to have been made both in British and German territory along Lake Victoria, one being near the Lumbas Station of the Uganda Railway at mile 520, and the other in German territory to the east of Speke Gulf.

IN the course of a recent article published in the *Recueil de l'Institut botanique de Bruxelles*, Prof. Errera comes to the conclusion that it is not possible for organisms to exist of a size very appreciably smaller than those which can be observed with the highest powers of the microscope now in use. An estimation is made of the number of molecules of certain bodies, such as albuminoids, which are present in a bacterium of given size: the number is of such an order of magnitude that only a few molecules could be present in an organism having a diameter $0{\cdot}01\mu$, and thus a minimum limit to the possible size is obtained.

THE geology of Kalahandi State, in the Central Provinces of India, is described by Dr. T. L. Walker (*Mem.* Geol. Surv. India, vol. xxxiii. part iii.). The entire State is made up of unfossiliferous rocks, mainly crystalline schists, with occasional masses of laterite which cap the broad hills in the south-eastern part of the State. The occurrence of graphite, which may be of commercial importance, is noticed, and it is remarked that the graphite-bearing rocks may become diamond-bearing in places where they have been subjected to intense pressure. In sands from the streams near Bondesor, minute crystals, regarded as diamonds, have been detected.

ALTHOUGH several accounts of the cytological changes which accompany the formation of eggs in the Saprolegniaceæ have been published, the lack of agreement in details and conclusions made it desirable that further evidence should be obtained. This is forthcoming in the experiments and histological investigations which are recorded by Prof. B. M. Davis in the *Decennial Publications* of the University of Chicago. The experiments were conducted entirely with plants bearing oogonia only. A peculiar feature is the appearance of specialised masses of cytoplasm, the cœnocentra, round which the eggs are formed, and which influence the destiny of the nuclei.

A RECENT issue of *Psyche* contains the full report of a lecture by Mr. F. M. Webster on the "diffusion" of insects in North America. It is pointed out that this diffusion commenced far back in the Tertiary period, and attention is directed to the intimate connection between the insects of North America, northern Asia and Europe which existed at that epoch. Very remarkable is the fact that the modern Rhynchophora of North America agree more closely with their European Tertiary representatives than they do with those of their own country. All this indicates the probability of a former free intercourse between America and Asia, and perhaps also between America and Europe *viâ* the north-east. The lines of insect diffusion on the American continent are treated in some detail.

THE heredity of albinism forms the subject of a paper by Messrs. Castle and Allen published in the *Proceedings* of the American Academy. The experiments, which were made with mice, guineapigs, and rabbits, serve to show that albinism, at least in domesticated animals, is not, as often supposed, a sign of weakness and want of vigour. The important result is, however, the proof that albinism, as indicated by its disappearance for a generation and its subsequent reappearance under close breeding, is inherited in conformity with Mendel's law of heredity, and that, in the terminology of that law, it belongs to the category of recessive phenomena. For instance, in the case of mice, it has been demonstrated that the grey hybrids produced by crossing grey with white mice, when bred *inter se*, gave birth to grey and white offspring approximately in the Mendelian ratio of three to one.

IN the *Monthly Review* for June Sir Herbert Maxwell reviews the question of animal intelligence; that is to say, the psychology of animals other than man. Commencing with the declaration that he has nothing new to communicate, the author proceeds to observe that the problem resolves itself into three items. (1) Are animals born as automatons, and do they continue as such throughout life? (2) If they are conscious, are their consciousness and intelligence merely the physical products of certain changes which take place during development, and therefore spontaneous in the sense that the development of organic tissue is spontaneous? (3) Is the conscious intelligence esoteric, that is to say, due to the action of an external and superior mandate, or suggestion, acting upon a suitable physical receptacle? After relating a number of instances of animal behaviour bearing upon it, Sir Herbert considers it probable that the first question should be answered as follows, namely, that at birth animals are sentient and unconscious automatons, but that they are also provided with mental machinery ready to respond in a greater or less degree to

external impressions. In regard to the second question, evidence is adduced to show that, although the growth of the organ of consciousness may be considered spontaneous and congenital, yet that there are instances where the intelligence of individuals displays a forward movement which may have important effects upon the habits of the race. As regards the third question, the author observes that if it be unphilosophical to attribute to a certain species of moth a knowledge of vegetable physiology, "what is left but to speculate whether the First Cause be not also a Directing Power, with means of communicating his mandates to the humblest of his creatures?"

IN the current number of the *Bulletin of the American Mathematical Society*, Mr. E. B. Wilson reviews a very interesting work, Prof. G. Loria's "Ebene Curven," which ought to attract all classes of mathematicians. Besides giving an account (illustrated with numerous figures) of a large number of special plane curves which are of interest for historical or other reasons, Prof. Loria gives a summary of his memoir on panalgebraic curves. A panalgebraic curve is one for which x, y and dy/dx are connected by an algebraic equation; in this class are included a very large proportion of all plane curves which have hitherto been studied, and the fact that Prof. Loria has demonstrated a considerable number of geometrical properties common to them all is very interesting and remarkable.

MESSRS. DAWBARN AND WARD, LTD., have published a booklet by Mr. H. Snowden Ward entitled "Profitable Hobbies," containing much useful information upon manual work of various kinds which can be successfully performed by amateurs.

BY arrangement with Messrs. Kegan Paul, Trench, Trübner, and Co., Ltd., the Rationalist Press Association has published, through Messrs. Watts and Co., a sixpenny edition of J. Cotter Morison's "The Service of Man. An Essay towards the Religion of the Future."

IN the *Physikalische Zeitschrift*, No. 16, p. 457, Messrs. Elster and Geitel discuss the question of the cause of the electrical conductivity of the air in the neighbourhood of phosphorus undergoing slow oxidation. Experiments are described which indicate that the cloud rising from the surface of the phosphorus is not responsible in any way for the electrical conduction. It is also rendered probable by suitably devised experiments that the conductivity is really due to ionisation of the air in the neighbourhood of the phosphorus.

IN a recent investigation of the properties of colloidal solutions by Mr. H. Garrett, experiments on the viscosity of solutions of gelatin, silicic acid and albumin have been made which appear to throw considerable light on the nature of such systems. They behave like heterogeneous liquids composed of two solutions having a surface tension at the contact surfaces. At any given temperature the viscosity of these solutions is not constant, since this depends on the surface tension, and this again is a variable depending on the previous history of the solution.

A NEW refractory material, to which the name "Siloxicon" has been given, is now being manufactured on a large scale by the International Acheson Graphite Company at Niagara Falls. It contains silicon, oxygen and carbon, and is said to give most satisfactory results as a substitute for refractory clays, magnesia, lime and graphite in their application to high temperatures. The product is obtained by the action of carbon on silica at a temperature of 4500–5000° F. in the electric furnace, the quantity of carbon employed being insufficient for the complete reduction of the silica and its conversion into carbide. It is stated that in these circumstances compounds containing all three elements are obtained.

THE current number of the *Journal of Physical Chemistry* contains an interesting paper by Messrs. Miller and Kenrick on the subject of the identification of basic salts. The allocation of formulæ to basic salts is apt to be somewhat arbitrary, and there is no doubt that many of the "amorphous finely-divided precipitates" which have been endowed with formulæ and thus raised to the dignity of chemical individuality are nothing more than mixtures of different bodies in proportions dependent upon the conditions of preparation. The authors show that, at any rate for those precipitates the equilibrium of which with the mother-liquor is attained, the question of individuality can in many cases be solved by simple application of the phase rule. The considerations brought forward have been applied to establish the individuality of several basic salts which have been investigated.

IN the current number of the *Comptes rendus* there is an account, by M. P. Lemoult, of the preparation and properties of dibromoacetylene. Tribromoethylene, which is easily obtained in quantity by the action of sodium ethylate upon symmetrical tetra-bromoethanes, is heated with alcoholic potash in the absence of air, and the dibromoacetylene collected under water. The distillation has to be carried out in a current of nitrogen, as the substance is spontaneously inflammable in air. Dibromoacetylene cannot be distilled, even in a vacuum, and under certain conditions may explode violently. Bromine and iodine give rise to C_2Br_4 and $C_2Br_2I_2$ respectively, and cautious treatment of the ethereal solution with moist air or oxygen gives rise to oxalic and hydrobromic acids. The first action would appear to be the addition of oxygen resulting in the formation of oxalyl bromide, which is then acted upon by the water present in the usual manner.

WE have received from Mr. H. Kondo, director of the Taihoku Observatory, Formosa, valuable results of meteorological or rainfall observations made at fourteen stations in that island and in the Pescadores in the years 1896–1901, also a discussion of the observations (in Japanese) accompanied by diagrams showing very clearly the general characteristics of climate, tracks of typhoons, &c. We extract the following values for Keelung and Koshun, on the extreme north-east and south respectively; these are stations of the second order, but at the central observatory hourly observations are recorded. At Keelung the mean annual maximum temperature is 75°·7, minimum 66°·6; absolute maximum 94°·6 in July, minimum 37°·4 in February; mean annual rainfall about 150 inches. At Koshun the corresponding values are:—mean maximum 81°·7, minimum 71°·1; absolute maximum 92°·1 in July, minimum 49°·6 in February; mean annual rainfall about 92 inches.

THE additions to the Zoological Society's Gardens during the past week include two Grevy's Zebras (*Equus grevyi* ♂ ♀) from Southern Abyssinia, presented by Lieut.-Colonel J. L. Harrington, C.V.O.; two Leadbeater's Cockatoos (*Cacatua leadbeateri*) from Australia, presented by Lady Katherine Coke; two Eastern Sarus Cranes (*Grus antigone*), two Thurgi Terrapins (*Hardella thurgi*), a Batagur Water Tortoise (*Batagur baska*), twelve Long-fingered Frogs (*Rana hexadactyla*) from India, five Wall Lizards (*Lacerta muralis*, var. *melisselensis*) from St. Andrae, a Magpie (*Pica rustica albino*), British, deposited; two Common Camels (*Camelus dromedarius*, ♀ ♀) from the Soudan, purchased; a Red-fronted Lemur (*Lemur rufifrons*), two Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE SOUTH POLAR CAP OF MARS.—In an article published in No. 4, vol. xvii. of the *Astrophysical Journal*, Prof. Barnard details the results of his observations of the South Polar cap of Mars made at Lick during the close approaches of the planet in 1892 and 1894. He made a series of micrometrical measures of the cap during each opposition, and the figures obtained during 1892 are set out in a table which accompanies the article.

Whilst looking over these measures recently it occurred to Prof. Barnard that if they were plotted with respect to the summer solstice of the Martian southern hemisphere some instructive results might be obtained. This was done, and the two curves, which are reproduced, show that the cap at both oppositions followed the same law of decrease with remarkable fidelity.

Another important point observed was that the cap appeared to diminish for some time after the summer solstice, that is to say, the highest temperature was not reached until several weeks after the maximum of solar heat; this may have an important bearing when discussing the existence of a Martian atmosphere similar to the earth's atmosphere.

In May, 1894, the Polar cap covered an area of about 365,000 square miles, by the end of November it had completely disappeared, thus showing that the snow, if snow it be, is not of any very great depth.

One remarkable phenomenon observed was the appearance of a projection from the edge of the cap in the same position and at the same period during each opposition; this remained behind as a bright strip, and seems to indicate the existence of a mountain range which is probably high enough to remain permanently snow-capped.

Eight drawings of the cap during each opposition, and a drawing of the whole planet, accompany the article, and show the details of the outline of the cap very clearly.

THE HARVARD PHOTOGRAPHS OF THE ENTIRE SKY.—In *Circular* No. 71 of the Harvard College Observatory, Prof. E. C. Pickering gives a description of the photographs taken at Cambridge (Mass.) and Arequipa, which have been obtained so as to furnish a bi-monthly record of the entire sky down to stars of the twelfth magnitude. Each plate measures ten inches by eight, and covers a region of more than 30 degrees square; they have been obtained with two similar anastigmatic lenses of one inch aperture and thirteen inches focal length.

Prof. Pickering explains how useful these plates have already proved at Harvard in determining changes of variable stars, the times of the first appearances of Novæ, &c., and states that in order to allow astronomical science generally to participate in these benefits, it has been decided to make negative copies on glass of one series of fifty-five plates, and distribute them to all who desire them at a price below cost. The whole set of fifty-five may be obtained for 15·00 dollars, and selected sets of ten for 3·00 dollars; the balance of the cost is being paid from the "Advancement of Astronomical Science" fund of the Harvard Observatory. Should the demand justify the experiment a second set, the centres of which are near the corners of the first set, will be issued later.

Prof. Pickering gives a catalogue of the plates it is proposed to issue, giving full particulars of the regions they cover, the dates of exposure, &c., and in a set of "remarks" appended to the catalogue he gives details of any special object each plate contains.

THE ROYAL OBSERVATORY, GREENWICH.

THE Report of the Astronomer Royal to the Board of Visitors of the Royal Observatory, Greenwich, was read at the annual visitation on Saturday last. From the record of work done during the year covered by the report, we select a few notes referring to the state of some investigations of especial interest.

Longitude Operations.—The second stage of the redetermination of the Paris-Greenwich longitude was completed in the autumn of last year. As in the first stage carried out in the spring and referred to in the last report, observations were made simultaneously by two French and two English observers at adjacent stations. The observations of both the French and English observers were made in three groups of three, six, and three full nights (or their equivalents in half nights), the observers with their instruments being interchanged between the first and second and again between the second and third parts. In the determination made in the autumn the stands were also interchanged with the instruments.

The reduction of the observations made by the English observers is completed with the exception of slight corrections which may have to be made in a very few instances to the assumed right ascensions of the stars.

The determination made in the spring of last year gave for the difference of longitude between Cassini's meridian and that of the Greenwich transit-circle 9m. 20·974s., and for the difference of personal equation $D-H=0·041$s. The determination made in the autumn gave 9m. 20·909s. and the difference of personal equation $D-H=0·049$s. In the first series, if the level determination had been based entirely on observations of the striding levels, the result would have been 9m. 20·982s., and if entirely on the observations of nadirs 9m. 20·969s. In the second series the difference between the results from "striding levels" and "nadirs" was only 0·002s. In the first series the probable error of the difference of longitude determined from one full night's observations was $\pm 0·040$s., and in the second series only $\pm 0·018$s., giving for the probable error of the determination made in the spring $\pm 0·0113$s., and for that made in the autumn $\pm 0·0047$s. In each series there was a double interchange of observers, so that the probable error includes any change of personal equation between the first and third parts, and this would appear to account to some extent for the larger probable error found for the first series.

The International Geodetic Association, considering it desirable that a redetermination of the difference of longitude Potsdam-Greenwich should be made with their lately adopted Repsold registering micrometer, the longitude pavilion was placed at their disposal, and the Post Office authorities have given all the telegraphic facilities desired. Prof. Albrecht and Herr Obst installed their instruments in the last week in April, and the observations are now in progress.

Lunar Tables.—The need for improved tables of the moon has been emphasised during the past year by the discussion of the results of Greenwich observations in the last ten years, which was taken up primarily in connection with the delimitation of an Anglo-German boundary, and may perhaps be advantageously extended with a view to its use in the formation of improved tables of the moon. In the same connection Prof. Newcomb, who has devoted so much attention to the subject, has urged that a fresh comparison should be made between theory and the Greenwich meridian observations from 1750 to the present time. It is a question for consideration whether it would be practicable to carry out this work at the Royal Observatory in such a form as would facilitate the preparation of improved tables and materially advance the lunar theory.

Stellar Observations.—The progress made in the observation of the reference stars for the astrographic plates, for which more than 10,000 stars are to be observed three times above and twice below pole, has been very satisfactory.

The observations of these stars were commenced in 1897 and will be completed at the end of 1906. In 6·35 years 63½ per cent. of the observations have been secured, of which 11½ per cent. were contributed in the last year. From a comparison of the observations above and below pole for the stars from N.P.D. 0° to 5°, which have been completely observed, it appears that the probable error of a catalogue place (five observations) does not exceed $\pm 0''·23$ in R.A. or N.P.D.

As the photography for the Greenwich Zone (Dec. +64° to the Pole) has been completed, only a few photographs have been taken with the astrographic equatorial to replace some which appeared to be inferior to the general standard. Altogether 116 photographs were taken during the year; these include 16 plates for the Astrographic Chart, 21 for the Catalogue, 48 of Nova Persei, 11 of Comet *b* 1902, 6 of Comet *a* 1903, and 8 for the adjustments of the instrument.

The counting of the Chart plates has been continued during the year, and completed between Dec. 64° and Dec. 70°. A paper on the statistics of the stars between 65° and 70° N. Dec. was communicated to the Royal Astronomical Society in January, and printed in the *Monthly Notices*.

The 28-inch refractor has been used throughout the year for micrometric measurements of double stars. The total number of double stars measured during the year is 381; of these 192 have components less than 1″·0 apart, and 105 less than 0″·5.

Series of measures have been obtained of κ Pegasi, δ Equulei, 70 Ophiuchi, and ζ Herculis. Capella has been examined at every favourable opportunity, and observations of the position angle of the elongated image have been secured on eight occasions.

Solar Activity.—Shortly after the date of the last report a long period of almost complete solar quiescence set in; from 1902 June 5 to September 17 inclusive, a period of 105 days, the mean daily spotted area was less than a single unit (one millionth of the sun's visible hemisphere). An active period set in on September 18 and lasted until November 28, 72 days, the mean daily area being 164 millionths. The rest of the year 1902 was very quiet, the remaining 34 days showing a mean daily area of only 3. In the present year the sun has been much more active, and has been free from spots on only 14 days since January 1, as compared with about 100 in the same period of last year. The first of a fine series of spot-groups appeared on the east limb on 1903 March 21, and a succession of new groups has followed almost without intermission up to the date of this report. There can be no doubt, therefore, that the solar activity is very decidedly upon the increase.

Tables and diagrams showing the distribution of sun-spots in latitude and the areas of sun-spots and faculæ compared with magnetic diurnal ranges for the 29 years 1874 to 1902 have been prepared, and will be published in the *Monthly Notices* R.A.S. for May.

Magnetic Observations.—The principal results for the magnetic elements for 1902 are as follows:—

Mean declination	16° 22′·8 West.
Mean horizontal force	4·0134 (in British units).
	1·8505 (in Metric units).
Mean dip (with 3-inch needles)	67° 3′ 25″.

Meteorological Observations.—The mean temperature for the year 1902 was 49°·1, or 0°·4 below the average for the 50 years 1841–90.

The rainfall for the year ending 1903 April 30 was 23·68 inches, being 0·86 inch less than the average of 50 years. The number of rainy days was 172. The rainfall has been less than the average for each of the eight years from 1895 to 1902 inclusive, the total deficiency for the eight years ending 1902 December 31 amounting to 28·91 inches. For the four months 1903 January–April there has been an excess of 0·95 inch.

THEORY OF CYCLONES AND ANTICYCLONES.

PROF. F. H. BIGELOW contributes to the U.S. *Monthly Weather Review* for February a paper on the mechanism of counter-currents of different temperatures in cyclones and anticyclones. An outline theory of the structure of cyclones and anticyclones was described in the report of the Chief of the Weather Bureau for 1898–1899 (vol. ii). It was evident, however, that a more complete insight into the mechanism of motions in a fluid such as air under atmospheric conditions would be afforded by the construction of systems of isobars on at least three planes having different altitudes. For this purpose, the sea-level and the levels of 3500 and 10,000 feet were selected, and since December, 1902, daily reduced pressures for these planes have been received from the regular observing stations of the United States and Canada, and charts have been constructed for them. The approximate gradients needed for a preliminary consideration of the subject have thus been obtained, and the general results of the investigation are stated by Prof. Bigelow as follows:—

(1) The cyclone is not formed from the energy of the latent heat of condensation, however much this may strengthen its intensity; it is not an eddy in the eastward drift; but it is caused by the counterflow and overflow of currents of different temperatures. Ferrel's canal theory of the general circulation is not sustained by the observations, nor is his theory of local cyclones and anticyclones tenable. There are difficulties with regard to the German vortex theory, but this is nearer the truth than the Ferrel vortex. The structure in nature is actually more complex than has been admitted in these theoretical discussions, but it doubtless can be worked out successfully along the lines herein indicated. (2) Regarding the relation of the upper level isobars to practical forecasting, it is noted as the result of the examination of charts that (*a*) the direction of the advance of the centre of the low pressure is controlled by the upper strata, and its track for the following twenty-four hours is usually indicated by the position of the 10,000-foot level isobars; (*b*) the velocity of the daily motion is also dependent upon and is shown by the density of these high level isobars; (*c*) the penetrating power of the cyclone is safely inferred from an inspection of the three maps of isobars of the same date; (*d*) there is decided evidence that areas of precipitation occur where the 3500-foot isobars and the 10,000-foot isobars cross each other at an angle in the neighbourhood of 90°; (*e*) there have been several cases in which the formation of a new cyclone has been first distinctly shown on the upper system of isobars before penetrating to the surface or making itself evident at the sea level. (3) It is expected that by completing our discussion of the temperature gradients between the surface and the higher levels we shall be able to secure daily isotherms as well as daily isobars on the upper planes, and this will tend to strengthen any further examination of these important problems. A suitable report will be prepared in which the data now coming into our possession will be subjected to a mathematical analysis and discussion.

ATMOSPHERIC VARIATIONS.

FROM the results of recent researches solar prominences seem to be playing a most important part, not only in the mechanism of the solar atmosphere, but in the variations of our own. Any investigation, therefore, that gives us new ideas or corroborates the old is most useful and valuable. In a previous number of this Journal (vol. lxvii. p. 569, April) an account was given of the results obtained from a research on the distribution of solar prominences as regards latitude. The prominence circulation thus disclosed that there was practically a law at work which the centres of prominence action followed, and this law, deduced from observations extending over the longest period available (1872–1901), was found to be in good agreement with that first suggested by Prof. Ricco in 1891 (*Mem. d. Soc. degli Spettr.*, vol. xx. p. 135). Prof. Bigelow has also been studying the question of prominence, facula and spot circulation, and in a recent number of the *Monthly Weather Review* (vol. xxxi. No. 1, p. 9) has stated his results. The method he adopted was somewhat different from the one first mentioned above, for the prominence circulation determined by him has been deduced by finding the mean variation of the prominence distribution resulting from coupling up together the values for those years which he considers are similar in relation to the eleven-year sun-spot cycle. Anyone familiar with this cycle knows the difficulty this involves, because it is only the mean length of the sun-spot period that is eleven years. Further, the epochs of maxima do not follow those of the minima at constant intervals, but vary from a little more than three to five years. In spite, however, of these probable sources of error, Prof. Bigelow deduces a circulation not very different from the one mentioned above, so that all the three computations and deductions show that there is a very definite movement in latitude and change in percentage frequency of occurrence from year to year.

A most interesting and important contribution, by Prof. T. H. Davis, to our knowledge of the fluctuation of the annual wind resultants, and indirectly to our knowledge of the movements of cyclones and anticyclones, appeared in one of the recent numbers of the *Monthly Weather Review* (vol. xxx. No. 11, p. 519). The investigation was restricted chiefly to stations included in the meteorological services of the United States and Canada, and the period discussed was the ten years 1891–1900. The results of the research

are best seen by consulting the map accompanying the paper, on which all the mean wind directions for each year and for each station are plotted.

Most interesting curves of wind resultants at Key West, Bermuda, Mt. Washington, and Pike's Peak are reproduced. Prof. Davis concludes by saying:—"The remarkable relations revealed by these tables and charts show that the natural relations of the winds are complex and still obscure. I see no indication of a sun-spot nor of a lunar influence. To what natural laws or combination of laws are we to attribute these variations in the annual resultants?" Perhaps, as a suggestion, Prof. Davis might correlate the variations of the wind directions in the southern stations with the barometric changes from year to year, which latter have recently been shown to be nearly identical with those in South America, and the inverse of those in the regions about the Indian Ocean and Australia.

In connection with the preceding paragraph, the paper by Prof. K. Kassner, on "Sonnenflecken, Depressionen der Zugstrasse V^b und Niederschläge". (*Annalen der Hydrographie und Maritimen Météorologie*, March) is of great interest. The author has analysed the variations in the yearly number of barometric minima which pass along this cyclone track, as specified by van Bebber, for the long period 1874 to 1901. He shows that the variations are in general agreement with an inverted sun-spot curve, that is, that there is a greater number of these low pressure areas at sun-spot minima than at the maxima. There are, however, several outstanding minor variations of shorter period.

A CAMERA FOR NATURALISTS.

We have recently had an opportunity of inspecting one of the "Birdland" cameras made by Messrs. Sanders and Crowhurst, of 71 Shaftesbury Avenue, to the design of Mr. Oliver G. Pike. Mr. Pike is well known as a specialist in the photography of birds and all that pertains to them, and so far as we, who are not specialists in this matter, are able to judge, the camera that he has designed is excellently adapted for the use of naturalists. Certainly no pains have been spared on the part of the makers to carry out Mr. Pike's ideas in a serviceable and practical way. The lens is a Goerz double anastigmat of 7 inches focal length, and by opening the front of the camera and drawing the lens forward, a change that is effected in a few seconds, the back combination may be used alone.

The range of focusing is sufficient to photograph objects within four or five feet even when the single combination is used, and the power that this provides in conjunction with the lens of twelve or thirteen inches focal length in getting large images will be appreciated by anyone who has attempted the photography of small animals. Focusing scales are affixed both for the complete lens and the single combination, though these would probably be rarely used, as the finder is a reflex arrangement that gives a full-size view of the image that falls upon the plate when the shutter is operated. An important point with regard to the finder is that its image can be seen when viewed from above, as usual, and also by looking horizontally when the camera is level with the eye. A mirror in the hood effects this desirable convenience. The shutter is the focal plane Anschutz, but with a device made specially by Messrs. Sanders and Crowhurst for linking it with the mirror within the camera that reflects the image upwards on to the finder screen. One release removes the mirror and operates the shutter, all the movements taking place smoothly and practically noiselessly. The camera is covered with a dull green leather, and all metal parts are bronzed, so that it forms an inconspicuous object in the ordinary surroundings of the country.

ENTOMOLOGY AT THE CAPE.[1]

The Cape has been described as the most magnificent natural museum of insect pests and parasitic diseases which the world possesses, and the report of Mr. Lounsbery for 1901 shows that, despite the dislocation induced by the war, he is making good use of his opportunities. The various reports show clearly the directions economic entomology is now taking—the introduction of parasitic species which prey upon the pests, particularly of ladybirds feeding upon aphis and scale—fumigation of infested plants with hydrocyanic acid or carbon bisulphide—and the compounding of different sorts of spraying mixtures. Mr. Lounsbery gives accounts of several attempts at the introduction of exotic ladybirds from California to keep mealybug, scale and American blight in check, though none of them have yet become established, as has, however, been successfully achieved with the Vedalia, which keeps *Icerya purchasi* in check. Various recipes for making paraffin emulsions are given; considering the efficacy of paraffin as an insecticide, and the difficulty that is always experienced in keeping it emulsified, it is strange that more trial is not made of the method devised by Mr. H. H. Cousins of increasing the specific gravity of the paraffin by dissolving naphthalene in it. Another section of economic entomology treated in this report is the investigation of a cattle tick which serves as an intermediary host for a parasite causing "heart water," a disease mainly affecting sheep and goats, and of another tick-propagated disease known as malignant jaundice of dogs.

One interesting application of modern methods which may be found here reported is the fumigation with hydrocyanic acid of gaols, asylums, and kindred public buildings to free them of the insect vermin which are so terribly abundant in South Africa.

[1] Cape of Good Hope Report of the Government Entomologist for 1901. Pp. 103. (Cape Town, 1902.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. A. C. Seward, F.R.S., has been reappointed University lecturer in botany. The University lectureship in midwifery is vacant by the resignation of Mr. Stabb. Candidates are to make application to the Vice-Chancellor before October 20. Mr. L. Doncaster, King's, has been appointed assistant to the superintendent of the museum of zoology.

The University College of South Wales and Monmouthshire, Cardiff, is proposed for adoption as an institution affiliated to the University of Cambridge.

Dr. Humphry, Dr. S. West, and Dr. W. Hale White have been appointed examiners in medicine; Dr. Herman and Dr. Handfield Jones examiners in midwifery; and Mr. Clinton Dent, Mr. E. Ward, and Mr. E. Owen examiners in surgery—for the third M.B. examination. Mr. F. C. Parsons, St. Thomas's Hospital, London, has been appointed an examiner in human anatomy. Mr. A. E. Shipley has been reappointed University member of the council of the Marine Biological Association.

A chair of agricultural botany has been established at the University of Rennes, and M. Daniel has been elected the first professor.

The late Alderman Benjamin Robinson, chemical manufacturer, bequeathed 500*l.* for scholarships in connection with the Royal Salford Technical Institute.

Dr. J. J. R. Macleod, assistant demonstrator of physiology at the London Hospital, has been appointed professor of physiology at the Western Reserve University, Cleveland, Ohio.

Dr. John Ryan has been appointed principal of the Paddington Technical Institute of the London County Council. Dr. Ryan was formerly professor of engineering at University College, Nottingham, and at University College, Bristol, and has for the past three years held the post of principal of the Woolwich Polytechnic.

The Edinburgh summer meeting, which was instituted in 1886 and held annually until 1899, is now to be resumed, and the course will extend from August 3 to 29. The meeting will be directed by Prof. Patrick Geddes, and will deal this year especially with a study of Edinburgh and its region. The requirements of Scottish and English teachers in nature-study will receive prominent attention, and a series of excursions to various places of interest will be held. Sir John Murray, Prof. J. Arthur Thomson, and

Mr. J. G. Goodchild are assisting in various departments. Communications should be addressed to the secretary at the Outlook Tower, Edinburgh.

A SUMMER meeting of university extension students will be held in Oxford in August, the first part being from August 1 to August 13, and the second from August 13 to August 24. The inaugural address will be delivered on Saturday, August 1, at 8.30 p.m., by the United States Ambassador. The programme of lectures is grouped in five sections, one of which is natural science. The list of lecturers includes the names of Dr. C. W. Kimmins, Mr. Michael Sadler, and Prof. Sims Woodhead. Conferences have been arranged on "The Education Act of 1902 and University Extension," chairman, Sir William Anson, M.P.; "Free Libraries and Popular Education," chairman, Lord Goschen, F.R.S.; and "Science in its Relation to Industry," chairman, Sir Philip Magnus.

THE President of the Board of Education has appointed Dr. H. F. Heath, Academic Registrar of the University of London, to the post of director of special inquiries and reports rendered vacant by Mr. Sadler's resignation on May 9. As the papers describing the circumstances which led Mr. Sadler to resign an office filled by him with such success since 1895, when it was created, have not yet been laid before Parliament, the appointment of a new director was unexpected, and will be received with surprise by the educational world. For eight years Mr. Sadler has been engaged in collecting materials for the study of educational systems and methods, and the information he has rendered available in his eleven volumes of special reports has been of the greatest assistance to students of educational science. But scientific method and thoroughness meet with little encouragement in this country, and though everyone seriously interested in education recognises the value of Mr. Sadler's work and understands its formative influence, it is evident that to the official mind the exigencies of the moment are of more consequence than scientific knowledge. It is to be hoped that the outcome of the affair will be to place the Special Inquiries Office on a firmer footing, and that the new director will be given increased facilities for the continued efficiency of the work carried on by Mr. Sadler.

THE programme of summer rambles for the present season, published in connection with the biology section of the Essex County Education Committee, and prepared by Mr. E. C. Horrell with the assistance of Mr. F. J. Chittenden, should prove very useful to teachers of nature-study. It is noteworthy that two distinct rambles in different parts of the county are arranged for each Saturday afternoon during June and July, so that a large number of teachers is given the opportunity of attending. Each ramble is conducted by a member of the biological staff. The excursions are intended to afford opportunities to teachers to gain experience in the methods adopted in the study of nature in the field. Any teacher is eligible who takes an interest in general natural history, and is prepared to devote a little leisure to its study. There is no fee, but teachers bear their own expenses. The advice given to intending ramblers is sensible and practical, as the following quotations show:—"Students must not needlessly uproot plants, tread upon crops, break through fences, or leave gates open." "The teacher should always bear in mind that most biological and morphological facts can be illustrated quite as satisfactorily by a common plant as by a rare one, and a plant should never be collected simply because it is rare." It would be difficult to devise a better plan to secure rational nature-study work in our schools than this way of first educating the teachers to become intelligent observers.

IN a letter to the *Times* of June 8, Mr. Sidney Lee draws an interesting and instructive comparison between American and British methods of appointing university professors. Of the superiority of the American plan there can be no doubt. In America, as soon as a vacancy arises in the professorial staff, the president of the university consults members of the faculty concerned. He invites their opinion as to who is the fittest man to fill the vacant chair. But the president does not confine his inquiries to his immediate circle of colleagues. Knowledge of the reputations that men are acquiring in academic work is wonderfully well diffused. The president who is seeking to fill a vacant chair has at command ready means of communication with presidents and professors of other universities. After due and thorough investigation, he forms his decision as to how the vacant post may be filled with greatest advantage to the institution over which he presides. He then forwards an invitation to the chosen person to occupy the vacant office. The procedure in vogue in this country is too well known to require description, and the only argument Mr. Lee has found in its favour is that it enlarges the electors' field of choice. "But," he remarks, "this argument is open to most serious question. Men of ordinary sensitiveness often refuse to submit themselves to the humiliating ordeal of public or semi-public competition for a vacant professorship, which in many respects reduces them to the level of advertising vendors of quack medicines. In effect the prevailing system often narrows the field of choice open to the electors, who are not in the habit of looking outside the panel of self-appointed candidates; it is, indeed, doubtful if honourable regard for the terms of their public advertisements permit them such a course of action."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 30.—"Preliminary Note on the Use of Chloroform in the Preparation of Vaccine." By Alan B. **Green**, M.A., M.D. (Cantab). Communicated by W. H. Power, M.D., F.R.S.

Briefly stated, the method of preparing vaccine by the chloroform process is described as follows:—Vaccine emulsion is first prepared by triturating one part by weight of vaccine pulp with three parts by weight of water. Through this emulsion, air charged with chloroform vapour is passed, with the result that the water of the emulsion becomes saturated with chloroform (1 in 200). After such saturation all excess of chloroform immediately escapes automatically from the vaccine, and the lymph is not brought into contact with a stronger solution of chloroform than 1 in 200. The extraneous micro-organisms originally present in the lymph are by this means killed in from one to six hours, while the lymph remains fully potent for vaccination. Vaccinations have been performed with lymph prepared in this way with highly successful results.

By the chloroform process, lymph, free from extraneous micro-organisms, can be distributed for use twenty-four hours after collection from the calf, instead of after the lapse of a month or longer, which is the time generally necessary for the elimination of these organisms by the glycerine process. The rapid preparation of lymph by the chloroform process possesses many obvious advantages.

Zoological Society, May 12.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Mr. W. B. **Tegetmeier** exhibited a skin and some illustrations of a species of pheasant from Mongolia recently described under the name of *Phasianus hagenbecki*. He suggested that it would make a handsome addition to our coverts.—Mr. Frank **Finn** spoke on variation in wild mammals and birds, and exhibited illustrative living specimens and drawings. The specimens included a frontlet of the barking-deer (*Cervulus muntjac*), bearing supernumerary antlers springing from the bony pedicles below the ordinary antlers; two abnormally-coloured Sambhar deer (*Cervus unicolor*); a goldfinch (*Carduelis carduelis*), showing red patches at the back of the head; and an albinistic variety of the ruff (*Pavoncella pugnax*), with head and neck nearly white.—Mr. F. E. **Beddard**, F.R.S., exhibited preserved and injected brains of mammals prepared in the Society's prosectorium.—Dr. J. F. **Gemmill** read a contribution to the study of double monstrosities in fishes. It contained an account of the anatomy of double monster trout-embryos, reference being made to the fusion, disappearance, or modification of organs which occurred at the region of transition from the double to the normal condition.—Mr. Robert **Gurney** dealt with the metamorphoses of the decapod crustaceans *Ægeon fasciatus*, Risso, and *Æ. trispinosus*, Hailstone. The larvæ of the two species were described, and comparisons made with those of other Crangonidæ, from which it was shown

that the known larvæ of the British Crangonidæ fell naturally into three groups, representing the genera Ægeon (which would include Cheraphilus), Crangon, and Pontophilus.—Mr. C. Tate **Regan** read a paper on the fishes collected by Dr. Goeldi at Rio Janeiro. Four species were described as new.—Mr. Martin **Jacoby** described fifty-six new species of South American Coleoptera of the family Chrysomelidæ.

Geological Society, May 13.—Mr. E. T. Newton, F.R.S., vice-president, in the chair.—On some disturbances in the Chalk near Royston (Hertfordshire), by Mr. H. B. **Woodward,** F.R.S. The disturbed Chalk near Royston, with its fractured and displaced flints, occurs in conjunction with Boulder-clay, and the latter is found beneath a considerable thickness of disturbed Chalk. While Boulder-clay occurs along the high ground bounding the disturbed area to the south, the undulating downs to the north are devoid of this Glacial Drift. The facts were to be explained, on the land-ice theory, if the ice were at first welded to the rubbly surface-strata in regions north of the escarpment, and, when movement set in, there were overthrusts of débris-laden ice, and upper layers of ice were rent asunder from and moved over lower ones; while to the thrust or long-continued pressure of ice along shear-planes at the higher levels may be attributed the belt of disturbed strata.—On a section at Cowley, near Cheltenham, and its bearing upon the interpretation of the Bajocian denudation, by Mr. L. **Richardson.**—Description of a species of Heterastræa from the Lower Rhætic of Gloucestershire, by Mr. R. F. **Tomes.** The specimen was obtained from Lower Rhætic Beds at Deerhurst (Gloucester). It occurred a little above the bone-bed; it is specifically new and generically new to the Rhætic, and it displays Jurassic relationships. It differs from the several Liassic species in the small size of the corallum and of its calices.

Royal Meteorological Society, May 20.—Captain D Wilson-Barker, president, in the chair.—Mr. C. P. **Hooker** read a paper on the relation of the rainfall to the depth of water in a well. In this he gave the weekly measurements of the depth of water in a well (101 feet deep) and the amount of rainfall at Cirencester, extending over the sixteen years 1887–1902. The depth of water in the well depends on how much rain penetrates, and the penetration is determined by the amount of rain, the rapidity of its fall, and the existing condition of the soil. The winter rains penetrate easily, and the summer rains with difficulty. Mere absence of rain is not the only cause of scarcity, deficiency of spring rains, and subsequent heat and evaporation being far more important factors. After the early spring months but little rain penetrates to the well, so that a timely forewarning at that season might prove of great value by enabling the existing supplies to be husbanded at an early period. Considering how narrow is the boundary between sufficiency and want, and looking to the fact that every year sees further demands made on our water supplies, the author considers that it is of the utmost importance that more attention should be paid to the storage of our surplus winter rains. This might be done by the formation of large hill reservoirs, and doubtless such measures as the reafforesting of large tracts of land would be of use in checking the rapidity with which the rains reach the rivers and are so lost.—Mr. W. **Marriott** gave an account of the frost of April, which was so keenly felt coming after the long spell of very mild weather in February and March. The fortnight April 12–25 was marked by keen northerly winds, great dryness, and low temperatures. Frosts on the ground were of almost nightly occurrence, and as the result, the destruction of the fruit blossom has been very great and also very general. In many places a good deal of the apple and strawberry blossom, although only in bud at the time, was killed, while potatoes were cut to the ground, and the foliage of horse chestnuts and limes much injured, particularly on the windward side.

Royal Microscopical Society, May 20.—Dr. Hy. Woodward, F.R.S., in the chair.—Mr. C. L. **Curties** exhibited a new monochromatic light apparatus, which was a modification of that shown at the November meeting by Dr. Spitta. It consisted of an optical bench carrying a Nernst electric lamp, aplanatic bulls-eye condenser, adjustable slit, achromatic collimating lens, a prism upon which was mounted a Thorpe replica grating, and an achromatic projection lens, the whole being fitted upon a mahogany base capable of being tilted. The spectrum given was exceedingly brilliant, and any part could be brought into the field of the microscope.—Messrs. W. **Watson** and Sons exhibited a new form of museum microscope placed inside a locked glass case through which the eye-piece projected. There was a circular disc in place of the ordinary stage, upon which twelve slides could be fixed; it was rotated from the outside, so as to bring each object into the field. Messrs. Watson also exhibited a bulls-eye condenser of long focus for photomicrographic purposes, fitted with iris diaphragm and centring adjustments.—There was an exhibition of pond life by fellows of the Society and members of the Quekett Microscopical Club.—It was announced that at the next meeting on June 17 there would be a communication from Lord Rayleigh on Mr. Gordon's paper on the Helmholtz theory of the microscope, and that Dr. H. Siedentopf would give a demonstration of his method of making visible ultra-microscopic particles in glass, and the application of the method to bacteria.

CAMBRIDGE.

Philosophical Society, May 4.—Dr. Baker, president, in the chair.—On Mendelian heredity of three characters allelomorphic to each other, by Mr. W. **Bateson,** F.R.S. The object of this note was to direct attention to various possibilities attainable by a modification of the Mendelian method. In the ordinary method the constitution of the gametes in the first cross (F_1) is tested by breeding such individuals *inter se* or with a pure recessive. The ensuing generation (F_2) will consist of a mixture of dominant and recessive individuals; but if the proportions depart from the expected 3 : 1 or 1 : 1, it is not possible to tell whether such departure is due to change in relative numbers of dominant and recessive gametes, to imperfect segregation of characters, or to change in dominance. This question can in part be answered by a method which consists in crossing F_1 produced from a parent having one dominant character with another heterozygous individual having a different dominant character (the same recessive being used in both cases).—On the diathermancy of antimonite, by Mr. A. **Hutchinson.**—On the potential difference between the terminals of a vacuum tube, by Mr. W. A. D. **Rudge.** The experiments described in the paper were made in a tube which contained a perforated and movable metal disc. It was found that the presence of the disc caused the potential difference between the ends of the tube to rise considerably above that of a perfectly similar tube without a disc. The increase varied with the nature of the metal; using different metals as discs, the order of increase was Pb 1, Ag 1·25, (Cu Fe Zn) 1·35, Al 3·5, Mg 3·8.—The determination of curves satisfying given conditions, by Mr. H. **Bateman.**—On the existence of a radio-active gas in the Cambridge tap-water, by Prof. **Thomson,** F.R.S. (see p. 90).—On a continuous spectrum, by Mr. T. H. **Havelock.**—On the Thomson effect in alloys of bismuth and tin, by Mr. S. C. **Laws.** The quantity of heat evolved or absorbed in consequence of the temperature gradient when a current C passes between two sections of a homogeneous conductor the difference of temperature of which is δT may be represented by $C\sigma\delta T$. These experiments comprise some measurements of the quantity σ—the specific heat of electricity—in bismuth and alloys of bismuth and tin. Some values for σ obtained in this way are:—bismuth 860 ergs per absolute unit current per 1° C.; alloy containing 1·3 per cent. tin 10,700 ergs per absolute unit current per 1° C.; alloy containing 6 per cent. tin 11,200 ergs per absolute unit current per 1° C.—A preliminary account of an investigation of the effect of temperature on the ionisation of gases acted on by Röntgen rays, by Mr. R. K. **McClung.** This paper gives some of the results obtained in a series of experiments made to ascertain what effect the heating of a gas has on the amount of ionisation produced in it by the action of Röntgen rays. The results obtained show conclusively that the amount of ionisation is independent of the temperature of the gas when the density of the gas is kept constant. Observations were made on air for a range of temperatures of nearly two hundred degrees from about 9° C. to a little more than 200° C. Carbon dioxide was also examined for a slightly wider range of temperatures, and precisely the same result was obtained as for air.

EDINBURGH.

Royal Society, May 5.—Prof. Geikie in the chair.—Mr. J. G. **Goodchild** read a paper dealing with (1) Scottish cairngorms, amethysts, and quartz, (2) chalcedony, opal and jasper, in which many interesting details were given of the valuable collection in the Museum of Science and Art. Important questions as to the genesis of these minerals and the influence of environment were indicated as calling for careful investigation.—Mr. J. G. **Goodchild** also read a paper on the phonetics of Gaelic, a subject to which he had devoted attention for many years. A specimen of Gaelic, which Prof. Mackinnon had put together as containing all the different sounds used in Gaelic, was transliterated in the phonetic alphabet known as palæotype, and each sound was then discussed, especially in relation to its mode of production. The author argued that many of the peculiarities of Gaelic sounds were due to the resonance in the vestibule or chamber immediately above the glottis.—Dr. A. T. **Masterman** gave a brief note on the heart and pericardium in Enteropneusta, Echinodermata and their allies, sketching what he believed to be the process of embryological development. One stage he had not, however, been able as yet to observe.—Prof. C. G. **Knott** communicated a further instalment of his investigations into the interrelations of the resistance and magnetisation of nickel at high temperatures. In the later experiments the temperature was pushed up to about 400° C. The increase of resistance of a particular wire when magnetised was found to increase as the temperature was raised, but afterwards greatly to decrease. This was to be expected if we suppose that the greatness of this effect in the magnetic metals is due to their magnetisation. At the highest temperature reached the percentage change of resistance in a moderate field was about one-sixtieth of the value at ordinary temperatures.

May 18.—The Hon. Lord M'Laren in the chair.—Dr. Alex. M. **M'Aldowie** read a paper on the human plantar reflexes. The lower limb in infants was a prehensile limb, and the reflex movement when the sole was tickled was similar to that in monkeys. As the child began to try to walk, the character of the reflex changed, and became ultimately plantigrade in type. The prehensile reflex, however, remained in abeyance, and manifested itself in disease. Under these conditions it appeared as soon as the cerebral control was withdrawn or overcome, and thus permitted the spinal control to reassert itself. It was a remarkable fact that such a reflex, which disappeared so early in the individual life, should reappear under pathological conditions. The author considered that this permanence of the prehensile reflex indicated that the period in the development of the ancestors of the human race when the lower limb was an organ of prehension was one of immense duration.—Sir William **Turner**, K.C.B., in a paper on the occurrence of the sperm whale or cachalot in the Shetland seas, described in detail the lower jaw, the teeth, and the tympano-petrous bones of a large specimen which had been found dead near Hillswick, Shetland, in August, 1901. The animal was a male, and was 61 feet long. The point of a massive explosive harpoon was found imbedded in the head, and had penetrated the great chamber for the lodgment of the spermaceti, most of which had consequently drained away. Of the sixty-four teeth obtained, forty-two were mandibular, seven were doubtful, probably mandibular, but had never cut the gum, and the remaining fifteen belonged to the upper jaw. They were of various shapes, straight and curved, and were obviously rudimentary and functionless. The paper contained a history of other occurrences of sperm whales in the Shetland seas, and closed with a comparative study of the tympano-petrous bones of Physeter, Kogia, and other Odontoceti.—In a preliminary note on the shedding of scales in gadoid fishes, Mr. Alex. Wallace **Brown** brought evidence in favour of the view that these fish shed their scales before spawning, and that this shedding ceases when the fish cease spawning. Should this fact be established by future investigation, the ordinary view that the rings on the scales indicate years of growth will have to be abandoned.

PARIS.

Academy of Sciences, June 2.—M. Albert Gaudry in the chair.—On certain singularities of partial differential equations of the elliptic type, by M. Émile **Picard**.—On some new fossils from the Soudan, by M. A. **de Lapparent**. Further fossils found by Captain Gaden in the Soudan are undoubtedly Cretaceous in type. One of them, an ammonite, is related to the genus Mammites and also to Vascoceras. The sea must thus have extended as far as Tchad, and covered the Damerghou. It is nearly certain that during the Cretacean epoch it joined the Atlantic, and that the whole of Africa north of 13°–14° N. latitude was occupied by a vast sea, from which the high lands of Abyssinia and an island including Aïr, Tassali, Ahaggar and Tademaït emerged.—Astronomical and magnetic work at Madagascar, by M. P. **Colin**. A series of measurements of the magnetic elements showed a diminution in the declination at Tamarive of 11′ between May, 1902, and April, 1903, with a slight maximum in September; the inclination diminished 1′ 45″, and the horizontal component diminished by 0·00033.—On the infinitesimal properties of linear systems of circles, by M. **Mesuret**.—On the anisotropy of silk, and on the value of Poisson's ratio for this substance, by M. F. **Beaulard**. The results of the measurements given show clearly that silk is not isotropic.—On the magnetism of liquids and crystals, by M. Georges **Meslin**. No solid belonging to the cubical system exhibits the phenomenon of magnetic dichroism.—On the heat conductivity of iron in the magnetic field, by M. A. **Lafay**. The experiment of Maggi, which would appear to show that the heat conductivity of iron is affected in a magnetic field, is a convection phenomenon due to the air, and is not observed in a vacuum. There is some experimental ground for supposing that in a very intense magnetic field the conductivity of iron for heat is appreciably diminished, but the effects do not vary with variations in the direction of the magnetic and heat flux.—On the utilisation of energy for transmission in wireless telegraphy, by M. G. **Ferrié**.—On the radiations emitted by radio-active lead, by MM. **Korn** and **Strauss**. On comparing the photographic effect of equal quantities of radio-active lead, in the form of sulphate, one of which had been exposed to the influence of the kathode rays for ten minutes, it was found that the action on the photographic plate was much more intense in the case of the exposed sample. This effect could not be due to phosphorescence, since the photographic action was unaffected by interposing a thin plate of aluminium or black paper. No other radio-active material appears to show this effect, which is remarkable in that there is no corresponding increase in the electro-active power, the rate at which an electrified body is discharged remaining the same.—On the emanation of radium and its coefficient of diffusion in air, by MM. P. **Curie** and J. **Daune**. The view of Rutherford that the emanation of radium behaves as a gas is confirmed by a fresh experimental method. The fact that the emanation of radiation is condensed at the temperature of liquid air, first announced by Rutherford, is also confirmed.—On the purification of hydrogen on the industrial scale by cold, by M. Ch. **Renard**. Crude hydrogen passed at the rate of one to two litres per minute through a vessel containing liquid air is completely freed from hydrogen arsenide. The method may be practically useful in the purification of hydrogen for balloons.—On the cementation of steel, by M. Léon **Guillet**. The velocity of penetration of the steel by the carbon depends upon the temperature, the time, and the nature of the substance supplying the carbon. By simple cementation certain nickel steels acquire the same hardness as carbon steels, when the cementation of the latter has been followed by tempering.—The decarburation of steels and thin metallic plates by evaporation in a vacuum, by M. G. **Belloc**.—On the form assumed by mercuric iodide on separating from solution, by M. D. **Gernez**. When mercuric iodide is formed either by volatilisation or evaporation from solution at low temperatures, the unstable yellow form is produced.—Observations on the precipitation of manganese by persulphuric acid in acid solution, by M. H. **Baubigny**. A study of the effect of varying the volume of the solution in which the precipitation is carried out.—The alloys of copper and magnesium, by M. O. **Boudouard**. In a preceding paper the study of the fusibility curve indicated the existence of three definite combinations: Cu_2Mg, $CuMg$, and $CuMg_2$. In the present paper these results are confirmed by a metallographic study of the alloys.—On the silicides of chromium, by MM. P.

Lebeau and J. **Figueras.** Four silicides have been isolated, corresponding to the compositions $SiCr_3$, $SiCr_2$, Si_2Cr_3 and Si_2Cr. Details of the preparation and properties of Si_2Cr_3 are given.—The electrolytic reduction of unsaturated acids, by M. C. **Marie.** By the use of mercury as a kathode, the unsaturated acids may be reduced to the corresponding saturated acids.—On dibromo-acetylene, CBr : CBr, by M. P. **Lemoult.**—On *Pyronema confluens*, by M. P. H. **Dangeard.**—On the botanical characters of the mycelium of the truffle, by M. Louis **Matruchot.**—The morphological characters of Pleurocecidia, by M. C. **Houard.**—On some fossil algæ in ancient strata, by M. B. **Renault.** As the result of a microscopical examination of boghead cannels the conclusion is drawn that these were formed by the accumulation of gelatinous algæ at the bottoms of lakes, each layer of coal being recognisable by the genus of algæ producing it.—On the present state of the volcano of Mont Pelée, by M. **Giraud.**—On the geology of the neighbourhood of Cinglais (Calvados), by M. A. **Bigot.**—On the graphical characters of fatigue in voluntary movements in man, by MM. A. **Imbert** and J. **Gagnière.**—The degradation of carbohydrates in the animal organism, by MM. A. **Bach** and F. **Battelli.** The theory is put forward that two alternating actions are at work, both produced by enzymes. The carbohydrates are first hydrolysed, with production of carbon dioxide, and then acted upon by an oxidising enzyme, with evolution of water. According to this view the carbon dioxide is never formed by direct oxidation, but by hydrolysis.

DIARY OF SOCIETIES.

THURSDAY, JUNE 11.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4.30.—The Bending of Eletric Waves round a Conducting Obstacle; Amended Result: H. M. Macdonald, F.R.S.—On the Propagation of Tremors over the Surface of an Elastic Solid: Prof. H. Lamb, F.R.S.—The Diffusion of Salts in Aqueous Solutions: J. C. Graham.—On the Structure of Gold Leaf, and the Absorption Spectrum of Gold: Prof. J. W. Mallet, F.R.S.—On Reptilian Remains from the Trias of Elgin: G. A. Boulenger, F.R.S.—A Method for the Investigation of Fossils by Serial Sections: Prof. W. J. Sollas, F.R.S.—An Account of the Devonian Fish, *Palaeospondylus Gunni*, Traquair: Prof. W. J. Sollas, F.R.S., and Miss I. B. J. Sollas.—The Measurements of Tissue Fluid in Man; Preliminary Note: Dr. G. Oliver.—Observations on the Physiology of the Cerebral Cortex of the Anthropoid Apes: Dr. A. S. F. Grunbaum and Prof. C. S. Sherrington, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—Quaternions: Major P. A. MacMahon.—Automorphic Functions and the General Theory of Algebraic Curves: Mr. H. W. Richmond.—Jacobi's Construction for Quadric Surfaces: Prof. G. B. Mathews.—Addition to the Papers on Four Known Simple Groups of Order 25920: Prof. L. E. Dickson.

FRIDAY, JUNE 12.

PHYSICAL SOCIETY, at 5.—Some Experiments on Shadows in an Astigmatic Beam of Light: Prof. S. P. Thompson.—The Positive Ionisation produced by Hot Platinum in Air at Low Pressures: O. W. Richardson.—On a Method of Determining the Viscosity of Pitch-like Solids: Prof. F. T. Trouton and E. S Andrews.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Eclipse of the Moon, 1903 April 11: F. W. Henkel.—Note on the Use of Peirce's Criterion for the Rejection of Doubtful Observations: S. A. Saunder.—On a Probable Relationship between the Solar Prominences and Corona: W. J. S. Lockyer.—Note on the Present Condition of the Lunar Theory: E. Nevill.—On the Relation between the Light Changes and Orbital Elements of a Close Binary System; with Special Reference to RR Centauri: A. W. Roberts.—Recent Observations of Mars and Jupiter: W. F. Denning.—The Spectra of Sun-spots in the Region B-D: Rev. A. L. Cortie.—Experiments as to the Actuality of the "Canals" observed on Mars: J. E. Evans and E. W. Maunder.—*Promised Papers*: Positions of 170 Stars around Nova Geminorum, and a Discussion concerning the Difference between two Exposures on the same Plate: F. A. Bellamy.—Examination of Mr. Whittaker's "Undulatory Explanation of Gravity" from the Physical Standpoint: G. Johnstone Stoney.—Observations of the Satellite of Neptune from Photographs taken with the 28-inch Refractor: Royal Observatory, Greenwich.—Mean Areas and Heliographic Latitudes of Sun-spots in the Year 1902, deduced from Photographs taken at the Royal Observatory, at Dehra Dun (India), and in Mauritius: Royal Observatory, Greenwich.

MALACOLOGICAL SOCIETY, at 8.—A List of Species of Mollusca from South Africa, forming an Appendix to G. B. Sowerby's "Marine Shells of South Africa": E. A. Smith.—On a New Genus, Planorbia, Moore, from the Albert Edward and Albert Nyanzas: J. E. S. Moore.—Notes on Some Jurassic Shells from Borneo, including a New Species of Trigonia: R. Bullen Newton.—Description of *Marginella lateritia*, n.sp., from the Andaman Islands: J. C. Melvill and E. R. Sykes.—New Mollusca from New Zealand: Rev. W. H. Webster.

MONDAY, JUNE 15.

VICTORIA INSTITUTE, at 4.30.—Annual Meeting.—Address by Prof. W. M. Flinders Petrie.

TUESDAY, JUNE 16.

ROYAL STATISTICAL SOCIETY, at 5.

ZOOLOGICAL SOCIETY, at 8.30.—On an Extinct Species of Genet (*Genetta plesictoides*) from the Pleistocene of Cyprus: Miss Dorothy M. A. Bate.—Description of a New Fish of the Gobiid Genus Rhiacichthys from British New Guinea: G. A. Boulenger, F.R.S.—Descriptions of New Reptiles from British New Guinea: G. A. Boulenger, F.R.S.—The Marine Fauna of Zanzibar and British East Africa, from Collections made by Mr. Cyril Crossland in the Years 1901 and 1902—Polychæta, Part II.: Cyril Crossland.

INSTITUTION OF CIVIL ENGINEERS, at 9.—"James Forrest" Lecture, Some Unsolved Problems in Engineering: W. H. Maw.

WEDNESDAY, JUNE 17.

ROYAL MICROSCOPICAL SOCIETY, at 8.—On the Theory of Optical Images, with Special Reference to the Microscope: Lord Rayleigh, F.R.S.—On a Method of making Visible Ultra-microscopic Particles in Glass, and the Application of the Method to Bacteria: Dr. H. Siedentopf.—On the Lag in Microscopic Vision: E. M. Nelson.

CHEMICAL SOCIETY, at 5.—(1) The Estimation of Arsenic in Fuel; (2) The Electrolytic Estimation of Minute Quantities of Arsenic, more Especially in Brewing Materials: T. E. Thorpe.—Crystallised Ammonium Sulphate and the Position of Ammonium in the Alkali Series: A. E. H. Tutton.—Action of Hydrogen on Sodium: A. Holt, jun.—(1) The Action of Halogens on Compounds containing the Carbonyl Group; (2) Reactions involving the Addition of Hydrogen Cyanide to Carbon Compounds: A. Lapworth.—The Acetoacetic Ester Synthesis: A. C. O. Hann and A. Lapworth.—Rimu Resin: T. H. Easterfield and B. C. Aston.—Note on the Karaka Fruit: T. H. Easterfield and B. C. Aston.

INSTITUTION OF CIVIL ENGINEERS, at 10 a.m.—Inaugural Address of the Engineering Conference: John Clarke Hawkshaw.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—The Meteorological Aspects of the Storm of February 26–27, 1903: Dr. W. N. Shaw, F.R.S.—The Dines-Baxendell Anemograph and the Dial-pattern Non-oscillating Pressure-plate Anemometer: Joseph Baxendell.

THURSDAY, JUNE 18.

ROYAL SOCIETY, at 4.30.—*Probable papers*: (1) Surface Flow in Crystalline Solids under Mechanical Disturbance: (2) The Effects of Heat and of Solvents on Thin Films of Metal: G. Beilby.—The Magnetic Expansion of some of the Less Magnetic Metals (with an Appendix by G. A. Schott): Dr. P. E. Shaw.—On the Discharge of Electricity from Hot Platinum: Dr. H. A. Wilson.—The Bionomics of *Convoluta Roscoffensis*, with Special Reference to its Green Cells: Dr. F. W. Gamble and F. Keeble.—New Investigations into the Reduction Phenomena of Animals and Plants: Preliminary Communication: Prof. J. B. Farmer, F.R.S., and J. E. S. Moore.—The Action of Choline, Neurine, Muscarine and Betaine upon Isolated Nerve (and upon the Excised Heart): Dr. A. D. Waller, F.R.S., and S. C. M. Sowton.—The Physiological Action of Betain Extracted from Raw Beet Sugar: Dr. A. D. Waller, F.R.S., and Dr. R. H. Aders Plimmer.—On the Physiological Action of the Poison of the Hydrophidæ; Part II. Action on the Circulatory, Respiratory and Nervous Systems: Dr. L. Rogers.—A Paper on the Spectra of Neon, Krypton and Xenon: E. C. C. Baly.—A Study of the Interaction of Mercury and Nitric Acid: Prof. P. Chandra Rây.—And other Papers.

LINNEAN SOCIETY, at 8.—Descriptions of New Chinese Plants: S. T. Dunn.—On the Life-history of a New Indian Species of Monophlebus: E. P. Stebbing.—On the Anatomy of Leaves of British Grasses: L. Lewton-Brain.—Scottish Freshwater Plankton.

FRIDAY, JUNE 19.

ROYAL INSTITUTION, at 9.—Radium: Prof. Pierre Curie (in French).

CONTENTS.

THURSDAY, JUNE 18, 1903.

A SCHEME OF VITAL FACULTY.

Human Personality and its Survival of Bodily Death. By Frederic W. H. Myers. In two volumes. Vol. i. pp. xlvi+700; vol. ii. pp. xx +660, including elaborate index. (London: Longmans, Green and Co., 1903.) Price 2*l.* 2*s.* net.

IN introducing this book to what must be regarded for the most part as a hostile audience, I would claim for it that it is a record of the life-work of a pertinacious and industrious student, in a region beyond the borderland of present orthodox science; and would explain that it has for its object the better comprehension and coordination of a multitude of human faculties, some of them recognised as real though obscure, others not yet generally recognised as existing. The phenomena of sleep, of genius, of multiple personality, of hysteria, of hypnotism, of hyperæsthesia, and of trance, are among those generally recognised by medical specialists and practically treated; though, in truth, most of them seem to be regarded chiefly or solely as pathological curiosities. The phenomena of sensory and motor automatism, of telepathy, and of clairvoyance, are not among the human faculties yet generally recognised. By long study Myers was able to accept them all, in various degrees, and he discerned a thread of connection running through them, so that he felt it possible gradually to design a comprehensive scheme which should include them all,—a building, as it were, in the composition of which each constituent filled its appointed place, so that no part was left forlorn and unsupported by adjacent materials, and so that the eye of science subsequently glancing over it might be willing to recognise the possibility and appropriateness of structures which when isolated had seemed strange and fantastic and incredible.

The construction of such a unified scheme, welding together phenomena often spoken of as occult with others which, though recognised by science, were difficult of interpretation and classification,—like genius, for instance, or hysteria in its many aspects,—was Myers's end and aim; and the result is embodied in two closely-printed volumes. Whether he has succeeded, it is for posterity and for psychologists to say. His treatment is not likely at once to commend itself to philosophers, and it is not as a philosopher that he writes; his treatment aims at being scientific, but it is unusual in being very distinctly literary in form. I shall not argue the matter, but shall content myself with giving such few extracts from the earlier portion of the book as may legitimately present to a critical audience the object and motive power of the whole treatise, a treatise on human personality and vital faculty, which, whether successful or not, is, at all events, more comprehensive and more ambitious than anything which has hitherto been attempted by man in that direction.

If the objection is made that Myers was not a man of science, he himself would have admitted it at once; but I am not so ready to admit it for him. Without the technical training, he seemed to me definitely to have many of the faculties and instincts and powers of a man of science, combined with such a mental grasp, vivid imagination, and power of expression, as would put most of us to shame.

However that may be, I would point out that men not professionally scientific have had a profound influence on scientific progress before now, and if I were to seek for an analogy to the effect which I expect these volumes will have upon the development of the psychical sciences, I would liken it by anticipation to the effect of the "Novum Organon" upon the physical sciences. Francis Bacon was a man of letters, not a scientific man, but he recalled all educated men to the possibility of exploration by experiment and observation, and so cleared the ground and paved the way for the general acceptance of the results of Gilbert and other great and truly scientific men of the same and subsequent eras, whose pioneering work might else have been lost in a mist of dislike, disbelief, and obscurantism.

Myers has shown that obscure psychical phenomena can be legitimately investigated by observation and experiment, and can be regarded as part of a sufficiently comprehensive scheme of natural knowledge; him, then, I liken to Bacon. If we ask who corresponds to the Gilbert of the same age in the psychical sciences, few of us would have any hesitation in bringing forward such names as those of Wallace and of Crookes.

In so far as it may be said that Bacon did not wholly appreciate the work of Gilbert, so we may say something similar of Myers's attitude to what he was constrained to consider the somewhat too trusting disposition of that eminent man Dr. Wallace; though of the more stringent methods and results of Sir W. Crookes he was keenly appreciative.

I am merely stating facts without comment, and will now content myself with a few explanatory and helpful extracts, showing Myers's recognition to the full of the importance of strictly scientific procedure, his appreciation of the stringency and value of scientific proof, and of the difficulties attending scientific investigation in so unknown and comparatively unexplored a territory as that of the psychical nature and spiritual faculties of man.

"The method which our race has found most effective in acquiring knowledge is by this time familiar to all men. It is the method of modern Science—that process which consists in an interrogation of Nature entirely dispassionate, patient, systematic; such careful experiment and cumulative record as can often elicit from her slightest indications her deepest truths. That method is now dominant throughout the civilised world; and although in many directions experiments may be difficult and dubious, facts rare and elusive, Science works slowly on and bides her time—refusing to fall back upon tradition or to launch into speculation, merely because strait is the gate which leads to valid discovery, indisputable truth. . . .

"It is my object in the present work—as it has from the first been the object of the Society for Psychical Research, on whose behalf most of the evidence here set forth has been collected—to do what can be done to break down that artificial wall of demarcation which has thus far excluded from scientific treatment precisely the problems which stand in most need of all the aids to discovery which such treatment can afford.

"Yet let me first explain that by the word 'scien-

tific' I signify an authority to which I submit myself—not a standard which I claim to attain. Any science of which I can here speak as possible must be a *nascent* science—not such as one of those vast systems of connected knowledge which thousands of experts now steadily push forward in laboratories in every land—but such as each one of those great sciences was in its dim and poor beginning, when a few monks groped among the properties of 'the noble metals,' or a few Chaldean shepherds outwatched the setting stars."

As an illustration of the temper of mind which Myers brings to bear, and conceives ought always to be brought to bear, to the understanding of obscure phenomena, I will take the case of witchcraft, and quote as follows:—

"The lesson which witchcraft teaches with regard to the validity of human testimony is the more remarkable because it was so long and so completely misunderstood. The belief in witches long passed—as well it might—as the culminant example of human ignorance and folly; and in so comparatively recent a book as Mr. Lecky's 'History of Rationalism,' the sudden decline of this popular conviction, without argument or disapproval, is used to illustrate the irresistible melting away of error and falsity in the 'intellectual climate' of a wiser age. Since about 1880, however, when French experiments especially had afforded conspicuous examples of what a hysterical woman could come to believe under suggestion from others or from herself, it has begun to be felt that the phenomena of witchcraft were very much what the phenomena of the Saltpêtrière would seem to be to the patients themselves, if left alone in the hospital without a medical staff. And in 'Phantasms of the Living,' Edmund Gurney, after subjecting the literature of witchcraft to a more careful analysis than anyone till then had thought it worth while to apply, was able to show that practically all recorded first-hand depositions (made apart from torture) in the long story of witchcraft may quite possibly have been *true*, to the best belief of the deponents; true, that is to say, as representing the conviction of sane (though often hysterical) persons, who merely made the almost inevitable mistake of confusing self-suggested hallucinations with waking fact. Nay, even the insensible spots on the witches were no doubt really anæsthetic—involved a first discovery of a now familiar clinical symptom—the *zones analgésiques* of the patients of Pitres or Charcot. Witchcraft, in fact, was a gigantic, a cruel psychological and pathological experiment conducted by inquisitors upon hysteria; but it was conducted in the dark, and when the barbarous explanation dropped out of credence much of possible discovery was submerged as well."

Myers's attitude to the in some quarters prevalent creed called spiritualism has been frequently misunderstood, but it is illustrated by the following extract:—

"A large group of persons have founded upon these and similar facts a scheme of belief known as Modern Spiritualism, or Spiritism. Later chapters in this book will show how much I owe to certain observations made by members of this group—how often my own conclusions concur with conclusions at which they have previously arrived. And yet this work of mine is in large measure a critical attack upon the main Spiritist position, as held, say, by Mr. A. R. Wallace, its most eminent living supporter—the belief, namely, that all or almost all supernormal phenomena are due to the action of the spirits of the dead. By far the larger proportion, as I hold, are due to the action of the still embodied spirit of the agent or percipient himself. Apart from speculative differences, moreover, I altogether dissent from the conversion into a sectarian creed of what I hold should be a branch of scientific inquiry, growing naturally out of our existing knowledge. It is, I believe, largely to this temper of uncritical acceptance, degenerating often into blind credulity, that we must refer the lack of progress in Spiritualistic literature, and the encouragement which has often been bestowed upon manifest fraud—so often, indeed, as to create among scientific men a strong indisposition to the study of phenomena recorded or advocated in a tone so alien from Science."

He then relates the rise of a society for investigating psychical matters in a new fashion, among eminent men at Cambridge, who felt that the time was ripe for an attack on superstition and on world-old legendary tradition concerning an unseen world and occult influences—the subject-matter, in fact, of all religion—by purely scientific terrestrial methods, and in the conviction

"that no adequate attempt had yet been made even to determine whether anything could be learnt as to an unseen world or no; for that if anything were knowable about such a world in such fashion that Science could adopt and maintain that knowledge, it must be discovered by no analysis of tradition, and by no manipulation of metaphysics, but simply by experiment and observation—simply by the application to phenomena within us and around us of precisely the same methods of deliberate, dispassionate, exact inquiry which have built up our actual knowledge of the world which we can touch and see. I can hardly even now guess to how many of my readers this will seem a truism, and to how many a paradox. Truism or paradox, such a thought suggested a kind of effort, which, so far as we could discover, had never yet been made. For what seemed needful was an inquiry of quite other scope than the mere analysis of historical documents, or of the *origines* of any alleged revelation in the past. It must be an inquiry resting primarily, as all scientific inquiries in the stricter sense now must rest, upon objective facts actually observable, upon experiments which we can repeat to-day, and which we may hope to carry further to-morrow. It must be an inquiry based, to use an old term, on the uniformitarian hypothesis; on the presumption, that is to say, that if a spiritual world exists, and if that world has at any epoch been manifest or even discoverable, then it ought to be manifest or discoverable now."

As to the objection frequently urged against psychical investigation, on the ground of the asserted triviality and apparent worthlessness of some of the faculties which are the object of study, Myers says:—

"In investigating those faculties we have been in no wise deterred by the fact of the apparent uselessness of some of them for our waking ends. *Useless* is a pre-scientific, even an anti-scientific term, which has perhaps proved a greater stumbling-block to research in psychology than in any other science. In science the *use* of phenomena is to prove laws, and the more bizarre and trivial the phenomena, the greater the chance of their directing us to some law which has been overlooked till now."

Before embarking on his long and laborious quest—the enumeration and dissection of instances and the finding of a hypothesis that should fit and weld them all together—he concludes this part of his introduction with the following modest claim:—

"The truest success of this book will lie in its rapid supersession by a better. For this will show that

least I have not erred in supposing that a serious treatise on these topics is nothing else than the inevitable complement and conclusion of the slow process by which man has brought under the domain of science every group of attainable phenomena in turn—every group save this."

In the belief that this book marks an epoch in the history of psychical science, and that it will ultimately react with beneficial effect on the progress and enlargement of the scope of science generally, I venture to introduce this life-work of my friend to the readers of NATURE, or at least to such of them as are not already familiar with the subject.

OLIVER LODGE.

SCHOOL GEOMETRY REFORM.

A School Geometry. Parts i. and ii. By H. S. Hall, M.A., and F. H. Stevens, M.A. Pp. x + 140. (London: Macmillan and Co., Ltd., 1903.) Price 1s. 6d.

Experimental and Theoretical Course of Geometry. By A. T. Warren, M.A. Pp. viii+248. (Oxford: the Clarendon Press, 1903.) Price 2s.

Elementary Geometry. By Frank R. Barrell, M.A., B.Sc. Section i., part i., pp. xi +116. Price 1s. Section i., part ii., pp. vii+117 to 168. Price 1s. (London: Longmans, Green and Co., 1903.)

Solid Geometry. By Dr. Franz Hocevar. Translated and Adapted by C. Godfrey, M.A., and E. A. Price, B.A. Pp. vii + 80. (London: Adam and Charles Black, 1903.)

A PERSON may be a Cambridge Wrangler, and yet unable to make a simple graphical construction with accuracy. The ordinary schoolboy's knowledge of practical geometry is generally worthless or nil, and his knowledge of pure geometry, the result of his premature encounter with Euclid, is of like character.

But this state of affairs is being rapidly changed. As Messrs. Hall and Stevens say in the first volume of their new geometry, "The working of examples should be made as important a part of a lesson in geometry as it is so considered in arithmetic and algebra."

The book contains an excellent collection of easy graphical and deductive exercises, many of the examples requiring numerical answers. The latter are given at the end. A boy working through this course should acquire a working knowledge of geometry, and a fair insight into the methods of deductive logic.

The volume contains the substance of Euclid book i., and is based on the recommendations of the Mathematical Association; the sequence of Euclid is in the main adhered to. There are two parts, the latter dealing with areas. In this the experimental course is incorporated with the deductive exercises, and assigned equal importance with the latter. This is a good feature, and is to be continued in a further volume which the authors have in preparation. In the present case, it seems to be a defect that the plan has not been carried out to the same, or even a greater, extent in part i., which is concerned with lines, angles, and rectilineal figures. Here it would appear to be especially necessary to make the experimental course predominate. But the subject of school geometry is in a state of transition, and the authors have probably thought it well to proceed cautiously.

Mr. Warren's volume is also based on the report of the Committee of the Mathematical Association. The course includes the fundamental properties of the triangle and circle. Ratio and proportion, similar figures, and polygons are likewise considered. The experimental treatment occupies the first half of the book, and in the second half the same ground is covered, the propositions being formally established by deduction.

The two volumes by Mr. Barrell comprise the first of three sections of a new school geometry which, when complete, will extend to Euclid xi. and the mensuration of the simple geometrical solids. It is written in accordance with the new syllabus of the Cambridge Local Examinations, and the report of the Mathematical Association. Part i. is intended to take the place of Euclid, book i. Part ii. corresponds with Euclid, book iii., 1–34, and also includes a portion of book iv. In the treatment adopted, the experimental and practical course is worked in along with the deductive geometry, and is always made subordinate to the latter. We should like to see the demonstrative geometry relatively less prominent. A feature to be noticed is that the author gives three meanings of a plane angle, in the last of which the angle is regarded as the plane space swept out by a line of indefinite length (one way) turning about one end; the amount of turning is not the angle, but the measure of its magnitude. The author is right in stating that this conception is implied in many of Euclid's phrases. The numerical answers of lengths and areas are given to three significant figures, and of angles to the nearest ten minutes. In the latter case decimals of a degree would perhaps have been preferable.

The actual personal use of mathematical instruments for graphical computations is probably largely foreign to many of the authors of the new text-books, and the treatment suffers on this account. There must be much future development before any text-book can be allowed to become crystallised.

Now that the study of pure geometry is to include numerical as well as graphical computations, it may become necessary, and it is certainly very desirable, to introduce simple tables of functions of angles so as to be able to solve right angled triangles completely, instead of being restricted as at present to the property of complementary angles and the use of Euclid i., 47.

The "Solid Geometry" by Dr. Hocevar will illustrate how this branch of the subject is presented to youths in Germany. Chapters i. and ii. deal with the properties of the line and plane in space, and the solid angle, but in a much less formal manner than is the case in Euclid xi. The remaining chapters relate to the properties and mensuration of the prism, cylinder, pyramid, cone, sphere and regular polyhedra. Exercises are provided in great variety, chiefly of the numerical type, and all necessary answers are collected at the end of the volume, where the reader will also find a useful index.

The translators say that, as the course of elementary plane geometry will be shortened on account of recent changes, teachers will be able to introduce solid geometry at an earlier period than formerly. The choice of the best complete school course of geometry is a very important matter at the present time. We should like to see solid geometry taught in connection with projection, and think that the elementary geometry of vectors should be introduced.

SHIP'S MAGNETISM.

Elementary Manual for the Deviations of the Compass in Iron Ships. By E. W. Creak, C.B., F.R.S., Retired Captain R.N. Pp. xii+150; with 4 charts. (London: J. D. Potter, 1903.)

IN his preface the author explains that the present work aims at being the successor of the "Elementary Manual" by the late Sir F. J. Evans. It is

"intended for the use of seamen of the Royal Navy and Mercantile Marine and Navigation Schools, and as an introduction to the Admiralty Manual for the Deviations of the Compass."

After a table of contents, there is a short introduction embodying some elementary definitions. Sections i. and ii., pp. 1–25, give an elementary description of the properties of magnets, with illustrations intended to supply a general idea of the action of the earth as a magnet, followed by a brief account of the phenomena of terrestrial magnetism which are of most importance to navigators. Section iii., pp. 26–42, describes the ordinary "Thomson" and liquid compasses and various auxiliary instruments. It also describes that temple of accuracy the Compass Observatory at Deptford, and gives valuable advice on such practical matters as the storage of compass cards, and the choice of a site for the standard compass on board ship. Sections iv. to vi., pp. 43–108, are mainly technical.

Section iv. treats of the "swinging" of ships to determine the deviations of the compass. It describes the sources of change in the deviation, more especially the effects due to "heeling" of the ship and to change of geographical position. It also gives some interesting particulars as to the large changes of deviation produced by the firing of heavy guns in warships. Section v. describes the effects of "soft" and "hard" iron. It introduces the reader to semicircular and quadrantal deviation by describing experiments whereby analogous effects can be produced by magnets or by soft iron situated near a compass.

Section vi. associates different constants in the ordinary mathematical theory of ship's magnetism—which the reader of the work is apparently intended to consult in the Admiralty Manual—with the action of imaginary magnets occupying specified positions in the ship. It then takes the actual results obtained in swinging certain warships, and shows how to construct deviation tables from them. This is done with great minuteness, and should be specially valuable to those who are unable to master the theoretical part of the subject. Section vii., pp. 109–131, treats of hollow iron spheres, Flinders bars, and other means of mechanical correction of the compass. There is a short account of the Peichl quadrantal corrector, which the author considers specially adapted for the case of compasses in conning towers of warships, where the earth's horizontal force is generally much reduced by the action of the ship's own magnetism. Amongst some concluding notes the author mentions the highly magnetisable and the nearly unmagnetisable alloys of iron recently discussed by Prof. Barrett and Mr. Hadfield as having a possible future in connection with compass work.

At the end of the book are some tables and a copious index. Table i. serves to facilitate the calculation of deviation tables. Table ii. tabulates some elementary trigonometrical functions. Tables iii. and iv. embody recommendations as to the dimensions of soft iron spheres and Flinders bars most suitable for the correction of deviation errors of assigned magnitude. At the end are charts of the earth's isogonal and isoclinal lines, and the lines of equal horizontal and vertical force, calculated for the epoch 1905.

So far, at least, as warships are concerned, the author's practical knowledge of the subject is probably unrivalled, and the value of the book as a mine of experience is hardly likely to be questioned. On the theoretical side there is more room for two opinions. The author takes a very humble—it is sincerely to be hoped too humble—view of the mathematical attainments of British navigators. His attitude to theory is the very antithesis of that of Mascart in his recent "Magnetisme Terrestre" (chapter xiv.). Mathematical results are occasionally introduced by a statement which does not amount to a complete proof, but might be mistaken for one, when a proof could be given without assuming advanced mathematical knowledge. Various of the references to magnetic and general theory scattered throughout the book are also capable of more exact statement from a physical standpoint.

The fact that the author defines the C.G.S. units in his introduction, but sticks to inches and other British or wholly arbitrary units in his text and charts, affords food for reflection. In one or two sections of the book there seem an appreciable number of minor misprints, more especially in one or two of the numerical examples, and attention might usefully be given to their elimination in the probable event of a second edition of the work being called for.

C. C.

OUR BOOK SHELF.

Encyclopaedia Biblica, a Critical Dictionary of the Literary, Political and Religious History, the Archaeology, Geography and Natural History of the Bible. Edited by the Rev. T. K. Cheyne, D.Litt., D.D., and J. Sutherland Black, M.A., LL.D. Vol. iv. Q to Z. Pp. xxxii+cols. 3989 to 5444. (A. and C. Black, 1903.)

THIS work, now completed, contains, as the publishers inform us, about as much printed matter as twelve volumes of the "Dictionary of National Biography." They have also published a thin-paper edition, which when bound in one volume is only about three inches thick. This encyclopædia has commanded for its

several departments the services of specially qualified writers, and will occupy for some time to come a high position as a work of reference for Biblical questions. As, however, it affords willing hospitality to the representatives of the most advanced criticism, it will be interesting in the course of a few years as a standard of comparison to show how far these opinions have been able to hold their own. Discussions of this kind occupy a large space even in geographical and historical articles and sometimes make it difficult to extricate physical facts from the maze of contradictory opinions. But these, when found, are clearly and accurately stated, as in the article "Trachonitis," which, however, is merely one of the more conspicuous of a large group. The maps also are a marked characteristic of the whole work—numerous, excellent of their kind, having in many cases contour lines and tints to indicate heights above and below sea level. That, for instance, which includes Trachonitis gives an excellent idea of the physical geography from north of Hermon to south of Pella in the Jordan valley. The short article on "Tabor" also is an admirable epitome of a place interesting both geographically and historically. That on "Tarshish" is a learned discussion on the identification of the place. In that on "Stones (Precious)" we find an almost exhaustive summary of what is known or conjectured about the gems of ancient times, with remarks on those in the high priest's breast-plate and the foundations of the vision city. The articles on natural history are not seldom from at least two contributors, one supplying the scientific the other the historical information. For the former, as under the word "Serpent," Mr. Shipley is responsible, so that we are sure of being on safe ground, while the other contributor adds much curious folklore. Indeed, the frequent references to this are not the least valuable part of the "Encyclopædia." Sir W. Thiselton-Dyer has contributed to the botanical articles, such as the "Vine," in this volume; that also on "Wine and Strong Drinks" is full of interesting information. Many of the theological and critical conclusions, as implied above, will doubtless be disputed, but as a compendium of information on history, archæology, geography, and all kindred topics the "Encyclopædia" is most valuable.

T. G. B.

Country Rambles: a Field Naturalist's and Country Lover's Note Book for a Year. By W. Percival Westell. Pp. xvi+312+xxxvi. (London: Henry J. Drane, 1903.) Price 10s. 6d.

Mr. Westell has made a serious mistake; he has let himself become the slave of his note-book. He seems to have made up his mind to write a year's diary for publication, with the result that he has filled it with trivialities which after a few pages will weary the reader, be he naturalist or not. On almost every page we find entries such as the following, which are taken quite at random:—"February 2. The snow will act as a deterrent on the singing of our feathered musicians, although I have often heard Robin and Wren singing in the very depth of winter, evidently cheered by the transient gleam." "March 21. I was tempted out into the garden early by the brilliant sunshine, and did a bit of gardening. Chaffinch 'pinking.' How delicate-looking the first Snowdrop as it peeps through the brown earth!" "June 10 (among other similar entries). What a variety of small beetles cross the path of the rambler, like dark little jewels darting about in the sunlight! There are many hairy caterpillars too. Cannot they move at a rate! How they curl up into the ball of protection!" No wonder that we read on the same page, "How often the Note-book comes out at this season!" Mr. Westell's mind has been working more upon his note-book than upon nature, and he would do well to leave it behind him for some time to come, and to reconstruct his ideas of observation and of a naturalist's work. When he touches a difficult or doubtful problem, he shows us at once what manner of naturalist he is. On p. 125 we read that "an instance is recorded by Herr Muller (*sic*), a well-known German Naturalist, of a Cuckoo sitting on, and hatching, her own fledgling. Three Cuckoo's eggs were found by Herr Muller in a hollow under a tussock of grass, &c." This statement seems to be taken from Dr. Japp's book on the Cuckoo; the Herr Muller is Adolf Müller, the forester; the occurrence he described, though, of course, in itself not impossible, has not been accepted by ornithologists whose opinions at any rate deserve some consideration, *e.g.* Prof. Newton, Mr. A. H. Evans, and Mr. Howard Saunders. Yet Mr. Westell retails this as a proved but extraordinary fact, without making the least attempt either to test the truth of it himself by going to the original source, or to collect the opinions of scientific naturalists on an alleged zoological fact of such great importance. He has to learn that there are other qualifications for a naturalist besides the constant companionship of a note-book and a binocular glass. We are very far from wishing to discourage the proper use of these, or the intelligent enjoyment and observation of nature, but what we cannot possibly encourage is the publication of bulky and expensive volumes like this (weighted, too, by photographs, only some of which are really excellent), which cannot satisfy the real naturalist or even the ordinary reader; and in this we are sorry to disagree with Mr. F. G. Aflalo, who has written a kindly preface to the book. It is to be hoped that Mr. Westell's love of the country and of nature will in the course of time be turned to better account.

Text-book of Organic Chemistry. By Prof. A. F. Holleman, translated by A. Jamieson Walker. Pp. xxvii+555. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1903). Price 10s. 6d. net.

A short time ago an English translation of Holleman's "Inorganic Chemistry" was welcomed by chemists in this country. The translation of the organic part has followed with commendable promptitude. This book is one of the best on organic chemistry which it has been our lot to read. Prof. Holleman approaches his subject with a freshness and vigour of style which make it delightful reading. Furthermore, he is not bound down by precedent or prejudice, and therefore follows no stereotyped style.

The book is written upon theoretical lines, and for this reason Prof. Holleman does not, as a rule, enter into descriptive details of manufacturing processes, and he only occasionally, as, *e.g.*, in the case of iodoform, describes even laboratory methods for preparing substances. This we consider is a good feature of the work—not that methods of preparation on a large scale should be neglected in teaching chemistry, but there are already many books which give *more* or *less* accurate details of manufacturing processes. And as for methods of laboratory preparation, these should be taught in the laboratory. Again, if the student is well grounded in his theory, as he should be if he carefully studies this book, he is less likely to look upon methods of preparation as if they were so many cookery receipts.

The book naturally falls under two heads, the aliphatic and the aromatic compounds. The aliphatic part is certainly more complete than the aromatic, which latter, considering that it contains, beside hydrocarbons of the benzene and naphthalene series, the terpenes, heterocyclic compounds such as pyrrole, furfuran, &c., and the albumens, is shorter than we should have

expected. The subject, however, is treated very concisely and generally very clearly. There is rather a want of lucidity, however, in his treatment of the synthesis of indigo on p. 512. The chapter on the diazo-compounds and the short *résumé* of Hantzsch's work in this direction are very good, and his remarks upon the electro-reduction of nitro compounds are also excellent.

Prof. Holleman pays particular attention to the physico-chemical side of the subject, an aspect which has been neglected by most writers of books on organic chemistry. On p. 188, for example, in the chapter upon polybasic acids, he devotes a long paragraph to their physical and chemical properties; again, on p. 196, he gives a clear explanation of the electro-synthesis of dibasic and other acids, while on p. 334 he describes Tafel's fine work on the electro-reduction of purine derivatives. In fact, one of the chief values of the work is the welding together of physical and organic chemistry.

The book is hardly suitable for beginners or for students who *want* (we will not say require) just a smattering of organic chemistry, but for the earnest student of the subject the work is one which can be most highly recommended. The style is good, the method of arrangement is excellent, and we think that there are few who will lay down the book after having studied it and feel disappointed.

Messrs. Wiley have produced the book in excellent style, and have spaced out the formulæ and equations in a lavish manner. Truly science knows no nationality—the book is written by a Hollander, translated by a Scotchman, and published by an American house.

F. M. P.

Education in Accordance with Natural Law. Suggestions for the Consideration of Parents, Teachers, and Social Reformers. By Charles B. Ingham. Pp. xi+125. (London: Novello and Co., Ltd.; New York: Novello, Ewer and Co., n.d.) Price 3s. net.

EVER since the publication of Rousseau's "Émile," with its well-known opening sentence, "Tout est bien sortant des mains de l'Auteur des choses, tout dégénère entre les mains de l'homme," there have been writers reflecting more or less satisfactorily the illuminating ray which Jean Jacques directed against the educational formalism of his day. Of course, if educational methods contravene the laws of nature, good results cannot be expected; but it is of supreme importance that writers venturing to define and formulate a system of education in conformity with natural law should at least first make sure that they understand the broad generalisations they call to their aid. An examination of Mr. Ingham's arguments gives rise to the suspicion that he has not completely mastered the conclusions at which men of science have arrived, and that his acquaintance with physical science is scarcely intimate. But Mr. Ingham is an experienced teacher, and has many sensible pieces of advice to offer, and even if the truths he advances are not new, they certainly are not universally adopted yet. To mention a few points on which the author has sound views is alone possible here. He advocates earnestly the need for more scientific methods in education; he pleads for more leisure time for boys and girls, in which they may follow their own devices; and he inveighs against the unsatisfactory early training of girls. He has not, we think, given science a sufficiently important place in the education of young people, but there can be little doubt that if parents could be persuaded to read the book they would have a clearer idea of what the aim of education should be.

A. T. S.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Psychophysical Interaction.

I AM interested by the letter of the professor of philosophy in the University of Birmingham on p. 126, and if your readers are not weary of the discussion—as I see no reason why they should be, since it is clearly a difficult question which must be discussed from time to time as science advances—I should like to add a few words.

When Prof. Muirhead says that my recent contention was advocated by Descartes, he is stating what is of interest, but what I did not know; I was not aware that the idea of energy, or even of momentum, was sufficiently clear in his era. But however this may be, he must not think that I regard the statement "that mind cannot produce energy" as axiomatic. It is a question not of axiom, but of fact. It seems to me that live things *do not* generate energy and *do* direct it; so I assert this, not as a necessity of thought, nor as an idea for which I have a special predilection, but simply as an experience. If Descartes maintained the same thesis, so much the more likely is it to be true.

Inert matter—all matter is inert—matter devoid of life then let us say, moves (technically, is accelerated) when and because it is pushed from behind. Live matter moves or is impelled to move from other motives; it is urged by anticipation of the future sometimes, by gratification of appetite for instance, or by avoidance of pain, often. A typical case is a costermonger's vehicle propelled by a bunch of carrots, or by the blows of a stick applied in indiscriminate profusion. There is nothing like that in storm or cataract or tide; nor is there anything like it in motor-car or railway-train, unless we include in the machinery the mind of the engineer.

Prof. Muirhead recommends a pacification of the question in the ultimate *nirvana* of idealistic monism. I am disposed to acquiesce ultimately in this destination, but I feel that there is something more proximate to be attained first. Philosophers go so fast and so far, they do not give the scientific man a chance; he wants to study the landscape and grub by the roadside. The ultimate outlook is doubtless there, very fine and attractive, like the setting sun; but the traveller to the west has much to see and much to do, and a constant gaze too far ahead may only dazzle him and unfit him for his proper work on the terrestrial sphere.

OLIVER LODGE.

Oxford, June 12.

THE opponents are not getting into close quarters. Dr. Hobson was irreproachable, but the others are using the word "force" all through the discussion, although it is the most unhappy word anyone could use in a controversy about fundamental physical conceptions. Its object is to enable us to contemplate one aspect of an action while we dismiss the other absolutely from our minds, because, when we want to give all our attention to one of the two bodies concerned, it helps us to ignore the other as much as possible.

It is remarkable also that Prof. Minchin should write that "guiding or deviating forces," if they allow the universe to keep its total energy intact, "infallibly alter its total momentum." Prof. Ward seems to have said the same thing, and the curious error remains without specific contradiction. Yet anyone who remembers that if there are n particles in the universe, there are $3n$ velocities for a sprite to amuse himself by tinkering with, will agree that he must, indeed, be a stupid or self-willed sprite who could not arrange to keep Σmv^2, $\Sigma m\dot{x}$, $\Sigma m\dot{y}$, and $\Sigma m\dot{z}$ unchanged while he disported himself with variations of the other $3n-4$ integrals.

Though that is merely a mistake on a side issue, an example on it will serve to put clearly the two different points of view. Suppose that there are two bodies of equal mass $2m$ moving due north with velocities of 9 and 1

units respectively, and without mutual action. The total energy is $m(9^2+1^2)=82m$, the total momentum due north is $2m(9+1)$, that due east is zero. At 12 o'clock the sprite wills that the first body should diminish its velocity due north to 5 and get one of 4 due east, while at the same time the second shall increase its velocity to 5 due north and get one of 4 due west. The bodies obey the sprite, of course, and even though he has by no means confined himself to "guiding or controlling forces," the energy remains the same, for $m(5^2+4^2+5^2+4^2)=82m$, and the total momentum north is $2m(5+5)$, and that east is $2m(4-4)$, *i.e.* $20m$ and 0, the same as before.

Now suppose a materialistic philosopher had been observing all this. Before 12 o'clock his observations of the continued uniform motion of the bodies would have led him to conclude that there was no mutual action between them, *i.e.* the law of the force was that it was zero. At 12 o'clock he would observe a change, and if ignorant that there was a sprite, would conclude that some other system, unseen by him, had come into collision with his system. If he is assured this is not the case, he will be driven to the only alternative, viz. that at 12 o'clock the *law of the action between them* had suddenly changed. (For the philosopher to say that a *force* had acted on the balls at 12 o'clock would be merely another way of saying that their motion had changed, because the definition of force, derived from Newton's laws, is "that which changes the state of motion of a body." Hence, whether he thought the action was due to a sprite, to an external material system, or to a change in the law of action between the bodies, the statement that at 12 o'clock a force had acted on each would be equally appropriate, and whatever supposition be adopted, the force would have the direction and magnitude, viz. that deduced by Newton's laws from the observed changes in the motion.)

Replace the two particles by the entire universe, and the point in dispute is really this. The physicist says, the changes in the motion of each particle at any instant depend solely on the positions of it and all the other particles, *according to laws which do not change with the time.* The form of the dependence, too, shows that there is but one future course of the motion—κ.λ.π.ν.'s singular solutions do *not* come in—and that it only needs infinite mathematical knowledge to calculate, from the positions and velocities at 12 o'clock to-day, and the unalterable laws of mutual action, what every particle of the system will be doing at, say, 3 o'clock three hundred years hence.

It is open to anyone to deny this position, but he ought, I think, to state exactly how far he does deny it, even though he may not be able to state exactly what he wishes to substitute for it. What it seems to me necessary for Sir Oliver Lodge to deny is that these laws apply to living matter. He *must say* that if the motions of the material particles of which protoplasm is composed be examined (in conjunction, of course, with those of the rest of the universe), our materialistic philosopher would be compelled to conclude that a change in the law of action had taken place—just as he would in the case of the two particles, if he were certified that they composed the whole universe. The materialist philosopher would then, I imagine, be prepared to receive with attention, at all events, Sir Oliver's assurance that these extraordinary changes were due to an exertion of will- or psychic-power on the part of the protoplasm, and that the law of mutual action between the material particles was not changed at all—it was only "supplemented," I suppose he would say, by the action of mind on matter.

Whether this is really so or not is perhaps open to that reasonable doubt which may exist on any matter which has not been made the subject of conclusive experiment, and any man is entitled to say that he doubts whether an observation of the motions of live matter would not reveal something incompatible with the supposition that the "forces" acting on the particles of the universe are determined according to any fixed law, *i.e.* a law independent of the time.

It would be interesting, but inappropriate, to discuss how far such a supposition will help people in regard to "the efficacy of prayer and many another practical outcome of religious belief," the reality of which Sir Oliver and many others consider to depend on the attitude taken in regard to it. Practically the effect of a general adoption of the supposition would be that for many years to come it would be thought to have removed the difficulties, but after a time these would crop up exactly as before. When men became more familiar with the conception of spirit, they would ask of it also, *what laws it followed*, and in the mental, as in the physical world, the conception of a necessary law of operation would assert its absolute sway among the higher minds who make knowledge their object. For it is only that which is subject to law which can be the object of knowledge. That which is capricious can only be the subject of memory and conjecture. It is not in this direction that any permanent solution of difficulties is to be sought.

EDWARD P. CULVERWELL.

Trinity College, Dublin, May 28.

IN relation to the letters on "Psychophysical Interaction" appearing in NATURE, the initial questioning the discussion works back to is whether we are to recognise in mind the mere knower, or manipulator, as well, of animal action. In relation to such a questioning it may be of use to consider that what is inferred concerning mind as existing anywhere outside oneself is inferred by study of action displays. We possess no faculty which can directly become aware of the psychical outside oneself. It is in action we see it, if at all. The study of animal intelligence infers as to animal intelligence by seeing it in animal action. We meet with peculiar kinds of actions which seem to require intelligence for their origin; and therefore surmise as to animal intelligence. The observation holds of the human intelligences with which we come in contact. We can only get to know the mind of a man through his action that he acts intelligently; therefore he must be intelligent. A man may speak his ideas to us, and by his speaking convince us of his inlying intelligence; but in ultimate analysis talking is as much a muscular performance as walking. Or he may write his thoughts, and we by reading may see in what he has written that he has ideas; but if the mind is mere knower it cannot manipulate action to the writing down of ideas, and therefore this is effected in some other way. For all we may know to the contrary, the man vacant of mind may be more at large than we are apt to suspect, for by the mechanical hypothesis a man may talk rationally and yet not have ideas.

The mechanical hypothesis disposes of the actions of animals by the theory of their being fitted and adapted in reciprocal relation to environment by process of natural selection. Variations in action take place in species, and the species which are favoured with favourable variations in action in the long run survive. The theory explains many of the adjustments of animal action, but not all. There are instances to which the hypothesis can never extend, and they are the instances of action which are put in in circumstances where there is no scope for natural selection to work. Take, for instance, a man learning to play a cornet. The learning to play a cornet is the putting in of an action process, and as such is worthy of biologic consideration. The man learns to play the instrument by manipulating his breathing and fingering the keys. He studies the music before him, and internally, and mentally, decides upon the fingering which is appropriate. His breathing into the instrument is timed by his mental translation of signs given by the printed page. Each stage of his practising is revised by hearing. Where he plays a false note he goes back, and exercises extra attention to do better.

The entire action of players in a cricket field is action adjusted in relation to the motion of the ball. It is action determined by seeing. Deduct the seeing and it cannot be done. And cricket has not been long enough in existence for natural selection to have anything to do with it. So the editing of NATURE is an intelligent-mechanical process. Deduct the intelligence in that process, and it cannot be done. The expert conjurer, equilibrist, or trick cyclist depends upon the alertness of his sensations for the correctness of his performance.

Apparently in the whole proceeding of animal action, excepting the old established automatic, knowing, seeing, hearing, feeling, plays its part. Ants will eat sugar but not saccharin. The *taste* to them is not as sugar. So

the lion runs to his prey with his nose to the ground, and the action of the bloodhound is valuable on account of his fine scent. It seems with mind as mere knower and non-manipulator of action these performances could not be put through. A. Bowman.

144 Well Street, Hackney, May 26.

Musical Sands.

May I record the discovery of musical sands at places along the shore between Ramsgate and Kingsgate. The sand occurs in small patches close to the chalk cliffs, the largest patch being found at Joss Gap. In composition the sand is very similar to that of Studland Bay, but the individual grains are more polished, and the proportion of denser minerals far higher. Of course, the sand can only be experimented upon when it has been uncovered by the sea for a sufficient length of time to enable it to become dry, and it gives remarkable results when tested in the ordinary way—especially when placed in a china vessel and struck with a wooden plunger.

June 8. Cecil Carus-Wilson.

THE STUDY OF BACTERIAL TOXINS.

The study of the toxins produced by bacteria is one of the most important branches of bacteriological research. The solution of some of the main problems of immunity and disease depends upon the knowledge that can be gained with reference to the nature of the bacterial toxins and their mode of action upon the animal body.

The methods introduced by Pasteur, Koch, and other observers have rendered it possible to detect and to isolate the specific agents in a number of infective processes. The number of infective diseases that have been definitely associated with the action of bacteria is considerable, *e.g.* tuberculosis, cholera, diphtheria, typhoid fever, &c.

It was natural that the earliest attempts to prevent the invasion of the animal body by these microparasites should be based more or less on the principles of Jennerian vaccination. An attenuated virus, for example, was taken and used directly as a vaccine in order to produce, if possible, an active immunity to the disease in question. This system of protective inoculation was tested in a number of diseases, and notably in infective diseases of the lower animals. The anthrax vaccine employed for the protection of cattle and sheep is a typical example of such immunising methods, whilst in recent years analogous methods of protective inoculation have been extensively used in certain diseases of man.

The study of the microparasites associated with diphtheria and tetanus showed that organisms of this type possessed not merely infective but likewise marked toxic properties. It was further established that these toxic properties were the determining factors in the production of the graver symptoms in cases of diphtheria and tetanus. It therefore became apparent that in diseases of this order, the point of cardinal importance was to combat, if possible, the toxins produced in their course. The laboratory experiments made with the diphtheria and tetanus organisms demonstrated that the poisons were soluble products of the bacterial cells in question, and were excreted into the nutrient fluids in which they had been cultivated. These toxins were proved to be of a specific nature, as they reproduced the essential general symptoms of the diseases.

Diphtheria and tetanus are therefore intoxications of the body, due to the action of specific soluble poisons produced by the parasites at the seat of infection. The toxins, on being introduced into suitable animals in carefully regulated doses, produced an active immunisation of the animals characterised by the formation in their blood of anti-bodies as regards the toxins in question—in other words, antitoxins resulted. The antitoxic serum, when added to the toxin *in vitro*, robbed the toxin of its poisonous properties, and, probably in virtue of some chemical combination between toxin and antitoxin, a neutral mixture resulted. The serum containing these specific anti-bodies, on introduction into other animals, conferred on them a passive immunity. They were protected against the action of the toxin in question, and, most important of all, the serum was efficacious in the case of an already existing intoxication—it possessed curative as well as protective properties. If a large animal, such as a horse, was actively immunised by injection of the soluble toxins, considerable quantities of these antitoxic substances were formed and accumulated in its blood and blood-serum. In this way the serum of an animal highly charged with antitoxins became a valuable and innocuous vehicle for the introduction of these preventive and curative substances into the human system. The natural defensive forces of the body were thereby reinforced, and in the right direction. This method of serum therapeutics has had brilliant results in the case of diphtheria, and has been demonstrated to be a feasible therapeutic method in the case of tetanus. These maladies belong to the group of *intoxicative* diseases. There remained, on the other hand, a large number of diseases in which a general multiplication of the microorganisms in their host appeared to be the salient feature. It has been usual to call these, in contradistinction to the former, *infective* diseases. The successful results in the case of diphtheria led to the extensive study on similar lines of infective organisms generally. A systematic search was made for soluble bacterial poisons, as their detection would be likely to lead to valuable additions to antitoxic serum therapeutics.

The researches in this direction met with unexpected difficulties and disappointments. The results obtained in the case of diphtheria and tetanus were not found to be of general application. Each organism had therefore to be taken on its own merits, and individually studied. It speedily became apparent that, as regards a considerable number of infective agents, the conditions were not the same. On cultivation in fluid media no distinct evidence of the production of soluble poisons could be obtained, or, if present, they were so in an inappreciable amount. The attempts, therefore, to produce antitoxins by the injection of such culture fluids into animals did not promise to be of much practical value. This, as a matter of fact, has proved to be the case; the various serums prepared were found to possess little or no curative value. Many infective organisms did not apparently produce their injurious effects through the agency of soluble toxins, and consequently curative methods based on the assumption resulted in failure. Research was thrown back once more upon the living infective agents, and the possibilities there might be of protecting the body directly against their invasions, or, in other words, of producing not a poison but a bacterial immunity. Bactericidal substances were found to be present in the blood of individuals who had passed through an attack of certain infective diseases, and the bactericidal action was specific as regards the infective agent in each case. For example, the blood of a patient recovering from typhoid fever is bactericidal to the typhoid organism. In the absence of soluble immunising products, there was a strong presumption that these substances were to be sought for within the bodies of the bacteria. The bacteria in that case, if injected directly into the system, would tend to produce an active immunisation of the body, and would reinforce the bactericidal properties of the tissues in specific directions. The method most generally favoured for this purpose was the in-

jection of killed cultures of the bacteria in question. The typical examples are the vaccines employed in cholera, plague, and typhoid fever for prophylactic purposes. The killed cultures of the several organisms are injected directly into the healthy individual in calculated doses, and the method is generally described as one of protective inoculation. In all these cases the immunising value of the vaccine appears to lie essentially in the dead bodies of the bacteria it contains. The active immunisation that occurs depends upon a solution of the dead bacteria by the blood and tissues, and a consequent liberation of any immunising substances peculiar to the cells. The properties developed by the blood of the treated individuals are antibacterial and not antitoxic, or if so only to a small degree. If one assumes that the properties of the blood in such instances are purely of a bacteriolytic character, there would be no protection necessarily afforded against any poisonous substances that might be present in the bacterial cells, and liberated from them in the process of their dissolution or in the course of the disease. Whatever the point of view, the conviction is now an established one that in a number of infective diseases it is the direct study of the specific cellular agents that will be most likely to lead to results of therapeutic value. The important conclusion has been arrived at that there are two kinds of bacterial poisons—soluble toxins, which are secreted by the bacteria, and cellular toxins, which are contained within their body substance. The toxins may be either extra- or intracellular. The diphtheria and tetanus poisons, already referred to, are examples of the first group, and are to be met with in the nutrient fluids in which the organisms are cultivated. The typhoid and plague toxins are examples of the second group, and are practically absent from the culture fluids in which the specific organisms are grown. The poisonous principles are contained within the bodies of the microbes. The dead bodies of typhoid bacilli, although destitute of all infective properties, are yet toxic when introduced into animals in virtue of the intracellular toxins they contain—the animals succumb to an intoxication.

In the case of many diseases formerly regarded as purely infective in character, it has now become apparent that, in addition to the infective, the poisonous properties of the invading bacterial cells have to be taken into account. Any therapeutic endeavours of a curative character, it appears to the writer, ought therefore to be based on the presumption that every infection implies, sooner or later, an intoxication.

The number of infective organisms in connection with which research has failed to demonstrate soluble toxins of possible clinical importance is considerable. The presumption in such cases is that the missing toxins are intracellular, and that if antitoxic principles of treatment are to be devised they must be based on a knowledge of the nature and properteis of these cellular poisons. A vital question consequently for bacteriologists at the present moment is the relation of intracellular toxins to immunity. The study of the intracellular constituents of bacteria has, it will be obvious, assumed great importance on account of the issues involved. It is interesting to note, by way of parenthesis, how generally biological research is being attracted to the direct study of the cell, and how widely it is being recognised that the processes of life, whether of a natural or a morbid character, are in their essentials of an intracellular nature. In this respect the researches of Buchner were of wide biological significance. They were suggestive of much more than a theory of a cell-free alcoholic fermentation of sugars. And in the bacteriological field the original investigations of Koch, and the preparation by him of tuberculin from the tubercle bacillus, drew general attention to the important results that might be obtained from the study of the bacterial cell and its constituents. Various methods are employed with this object in view. The killed cultures of bacteria may be used, and their physiological effects determined by injection into animals, or by chemical means extracts may be prepared from the organisms and their effects similarly tested, or mechanical methods may be adopted in order to obtain the fresh intracellular juices.

In the investigations carried out by the writer, in conjunction with Mr. Rowland, during the past four years, mechanical methods were selected as the best adapted for the general purpose in view, viz. the study of the intracellular toxins and ferments of bacteria and other cells. The first essential was the elaboration of a method to obtain the plasma of such minute cells as the bacteria. The aim was to procure the fresh cell juices and to avoid their possible modification by heat or by chemical agents. For this purpose the cells were mechanically triturated by a *cold* grinding process. The necessary cold was most conveniently obtained by the use of liquid air. It was found that the cells could be mechanically broken up when in the brittle condition produced by immersion in liquid air, without any admixture of sand or other foreign substances. A number of bacteria and other cells have been triturated in this fashion, and their fresh intracellular constituents obtained. The results in the case of the typhoid bacillus will serve to illustrate the general line of research being followed. The typhoid organisms were grown on ordinary beef broth agar, and after careful washing with distilled water were disintegrated in a mechanical contrivance at the temperature of liquid air ($-180°$ C.). The disintegrated mass was freed from insoluble suspended particles by centrifugalisation, and an opalescent fluid, representing the cell-juices of the organism, resulted. The typhoid cell-juices obtained by this method, on inoculation into animals in small doses, invariably proved toxic or fatal. It was therefore concluded that the typhoid bacillus contains within itself an intracellular toxin and that it is possible to extract it from the organism.

The typhoid cell-juices were further tested for immunising and other properties, and were administered subcutaneously to suitable animals. The experiments showed that the serum of the monkey, after injection of the typhoid cell-juices, possessed antibacterial and antitoxic properties, inasmuch as the serum protected experimental animals against the typhoid bacilli, and also against the intracellular toxin obtained from them. The serum was found to possess curative and preventive properties as regards the typhoid bacillus and the intracellular toxin extracted from the same organism. The research thus afforded proof that in the case of one species of pathogenic bacterium, the intracellular juices of the organism, when injected into a suitable animal, give rise to the production of a serum which is both bactericidal to the organism itself and antitoxic as regards a toxin contained in its substance.

The results already obtained are such as to encourage further inquiry as to the possibility of their practical application in the case of typhoid fever, as well as to determine in how far such properties of the cell-juice are shared by other pathogenic microbes. The particular method employed has proved of value in the study of a distinct class of toxins and ferments brought to light by recent research which are contained and operate within the cell and bacterium, in contradistinction to the well-known class of toxins which are extracellular, *i.e.* extruded during life from the cell to the surrounding medium. The importance attached to the intracellular group of bacterial poisons is evidenced by the increasing attention that is now being paid to their study.

ALLAN MACFADYEN.

SCIENTIFIC KITE FLYING.

SYSTEMATIC observations of the temperature and humidity of the upper air have been made for many years past, both in America and on the Continent, kites being the means employed mostly in America, and kites and balloons on the Continent.

The plan adopted is to send up a kite of some 60 to 80 square feet of lifting surface, the line used being steel music wire instead of string, additional kites being attached to the line as occasion requires. The end kite, or the line close to it, carries a self-recording instrument, and in this way observations at a height approximating to or even exceeding three miles are sometimes obtained, although it is not often that the air motion in the various strata is such as to render a height of more than 10,000 feet possible. The obstacle to be overcome is the pressure of the wind upon the line, which soon reduces the angular altitude of the kite, and it is on this account, rather than on the greater strength of steel for the same weight, that steel music wire is preferable to string, the resistance of the wire on account of its smaller section being so much less.

FIG. 1.—Rhombus kite, 7 ft. 6 in. by 6 ft. by 3 ft. 6 in.

There are few days on which a small elevation may not be reached by a kite, but days really suitable are not plentiful. It is self-evident that a suitable wind is the first requisite, and to obtain a great height a suitable wind must prevail from the lowest to the highest strata reached. We cannot, of course, alter the wind, but fortunately we are able to move the point to which the kite line is attached, and this practically comes to the same thing as altering the force of the wind. The most convenient means of doing this is to fly the kites from the deck of a steam vessel, and during last summer observations were thus obtained for seven weeks almost daily.

The work was inaugurated by a committee of the Royal Meteorological Society, cooperating with a committee appointed by the British Association.[1] They hired a small steam tug of 55 feet length and 14 feet 6 inches beam. The vessel was stationed at Crinan, which is at the north end of the Crinan Canal, on the west coast of Scotland, and, Sundays excepted, kite ascents were made from her deck every day, no matter what the weather, from July 8 to August 26. The vessel could not steam more than seven knots, and the wind velocity necessary to raise a kite is from nine to twelve knots, so that on occasions when it was a dead calm no kite could be started. It happened, however, that no day was calm throughout, so that some time during the hours of daylight the opportunity of reaching at least 1500 feet elevation was afforded. Had the tug been capable of ten instead of seven knots, I have little doubt but that a height of 5000 feet might have been attained every day.

Using one or two kites only, no difficulty was experienced. The most troublesome point was getting the kite together when the wind was strong. The tug was small, and had no bulwarks, so that there was no shelter of any kind on deck, but her smallness was certainly an advantage in another way. A larger vessel would have produced eddies in the wind, and probably have rendered it difficult to start the kite direct from the deck. As it was we had no trouble, and it was very seldom that a kite failed to rise steadily from the starting point. In calm weather the vessel was

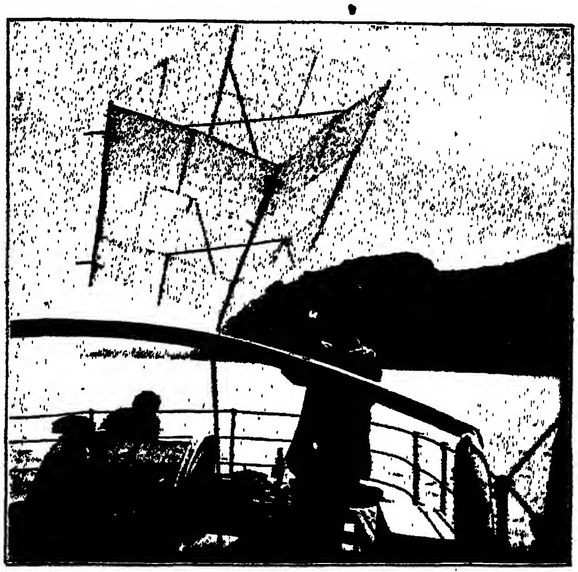

FIG. 2.—Starting a kite from the tug.

kept steaming against, or nearly against, the wind so as to produce sufficient relative motion to raise and maintain the kites. In rough weather she was taken out against the wind for some ten or twenty miles until a position was attained from which a clear run down the wind was possible, and the kite was then started. A wind of force 5 on the Beaufort scale is the most suitable wind for kite flying. This is known technically as a fresh breeze, and is sufficient to produce a moderate amount of white on the sea surface. One of the kites of the usual size for scientific kite flying will, in such a breeze, exert a pull of about 50 lbs. The wire used will bear a strain of some 300 lbs., and weighs about 16 lbs. to the mile, so that one kite in such circumstances will take nearly two miles of wire, and, if it be a good one, will raise the instruments to about 5000 or 6000 feet. The pull of 50 lbs. is well within the limits of stability of the kites, and is on the whole about the most convenient to work with, if one can be certain of the goodness of the kite. At Crinan the tug was so manœuvred that a tension of 40 lbs. for each kite on the line might be main-

[1] See paper on "The Method of Kite-flying from a Steam Vessel, and Meteorological Observations obtained thereby off the West Coast of Scotland" (*Quarterly Journal of the Royal Meteorological Society*, April).

tained, but kite flying is an art of which we were then without previous experience, and so it was well to err on the safe side. A steam vessel is extremely convenient for kite flying, as by altering either her speed or direction the strain upon the wire, provided the vessel is not already going full speed against or with the wind, can be varied with the utmost nicety.

With more than two kites difficulties often occur, owing to the fact that very different wind velocities may prevail at different heights. If the wind is greatest at the surface, adding more kites does not add appreciably to the height of the end one, since no kite can rise into a stratum in which it does not find sufficient wind. This sometimes occurred, but the more usual case was that the wind force increased too rapidly with elevation, so that if the tug were used to increase the relative surface wind to suit the lower kites, it added too much to the strength of the upper wind, and by unduly increasing the force upon the upper kites, put a dangerously high tension upon the wire. If, on the other hand, the tug were moved to suit the upper kites, the lower ones might be becalmed, and useless for lifting purposes, or perhaps even fall into the sea.

Very interesting results have been obtained from these experiments, both in America and on the Continent, but it has been felt that the conditions prevailing over the large oceans are very likely different from those over the continents. The cyclonic disturbances, on the motion of which our weather very largely depends, certainly show a preference for the sea, and it was in the hope that some light might be thrown on their mechanism, and the causes which produce them, that a locality on the west coast of Scotland was chosen for the observations. The evidence obtained from last summer's work is not sufficient to be conclusive, but so far as it goes it tends to show that as a depression approaches, the decrease of temperature with elevation becomes less than it was before. This was the case with every depression that passed while the experiments were in progress, and it leads to the conclusion that the upper air in the neighbourhood of a cyclone is relatively warm, and that the cyclones are convectional effects.

A further result of the observations shows that the temperature of Ben Nevis was in every instance below that of the free air at the same level some sixty miles to the south-west, often from 5° to 8° F. below. That the two air temperatures should have agreed was hardly expected, but the difference was very marked, and it is desirable that the experiments should be repeated in the same locality to confirm the result. The fact, however, that the summit of the mountain is so often wrapped in clouds, when the sky is clear elsewhere, tends to show that the summit must be unduly cold, and it seems likely that the effect is produced by the adiabatic cooling of the air as it is forced up the mountain slope. In fact, the cloud level on all the mountains and hills in the neighbourhood was always much below the point at which the kites entered the clouds. It is also known from the differences in the barometer on the Ben and the values computed from the Fort William readings that the temperature of the intermediate layers of air is not truly represented by the mean derived from the summit and sea-level temperatures.

England being so near the usual cyclonic tracks, observations on the upper air are of especial interest, and it is very desirable that a permanent station for the purpose should be established. It may perhaps be found that unmanned balloons too often fall into the sea to be usefully employed, but the attempt is well worth a trial, and so far as kite observations are concerned, the only difficulty is the financial one.

W. H. Dines.

A NATIONAL DIPLOMA IN AGRICULTURE.

A SO-CALLED national diploma in the science and practice of agriculture can now be obtained by any student who passes the necessary examinations. This diploma has undoubtedly a high-sounding title—it would be difficult indeed to suggest a title of greater weight—and it is therefore not surprising that the number of students entering each year for the examination is steadily increasing, and that successful students should be proud to write the important letters N.D.A. after their names. Now we greatly wish that a truly national diploma in agriculture could be obtained; that a well-ordered scheme of education and examination were authoritatively set forth; and that the skill and knowledge of the nation should be really brought to bear upon the subject. The diploma in question has no right to the title of "national." It is granted by a joint committee of two agricultural societies—the Royal Agricultural Society of England and the Highland and Agricultural Society of Scotland—it should therefore be designated "the agricultural societies' diploma." To claim for it a national importance, and thus to imply that it ranks above all other agricultural diplomas, is simply to mislead the public, and to assert a position to which it has absolutely no right. The question of continuing to grant the diploma in question has lately entered a critical stage; it may be of service, therefore, to set forth in few words the origin and character of the examinations on which it is based.

It must be reckoned as greatly to the credit of the two agricultural societies we have just named that they have been for many years engaged in promoting agricultural education by means of examinations. The Highland and Agricultural Society of Scotland was at the pains to obtain a supplementary charter in 1856 in order that it might add agricultural education to the other functions of the Society. This charter sets forth that "in order to encourage the proper education of agriculturists in Scotland" the Society is empowered to appoint a committee consisting of the professors of agriculture, anatomy, botany, chemistry, natural history, and technology in the University of Edinburgh, with sundry public officials, and seven members chosen by the Society. This committee is to appoint a board of examiners, and to grant diplomas bearing the corporate seal of the Society. The Society has acted on the powers thus given; it has conducted annual examinations in Edinburgh from 1858 to 1899, and granted diplomas according to the terms of its charter.

The Royal Agricultural Society of England possesses no such definite authority as that given to the Highland Society for the conduct of examinations or the granting of diplomas; its charter, given in 1840, merely authorises it "to take measures for the improvement of the education of those who depend upon the cultivation of the soil for their support." The Society has conducted annual examinations in England from 1868 to 1899. Up to 1897 the successful candidates received certificates, but in 1898 and 1899 diplomas were granted.

In 1897 the two societies nominated a joint board of examiners to conduct examinations in the science and practice of dairying, and annual examinations have since been regularly held both in England and Scotland. The successful candidates receive a national diploma in the science and practice of dairying.

In 1899 the two societies took a further step, and appointed a joint board of examiners to conduct examinations in the science and practice of agriculture; the examinations hitherto conducted by the separate societies then ceased. The first examination by the joint board was held in 1900, and such examinations

have since been regularly continued. The examination is always held in England. The successful candidates receive a national diploma in the science and practice of agriculture.

Such, then, is the history of the diploma of which we are at present speaking. It is, of course, obvious that any society or societies may hold an examination in any subject they please, and grant certificates to successful candidates; but may such bodies, without proper authority, presume to confer a national diploma? That is the serious question before us. The charter of the Highland Society undoubtedly authorises it to confer a diploma in agriculture in Scotland, but the language of its charter, which we have already quoted, clearly limits its authority to that country. This fact is so manifest that we are now told by the agricultural Press that the Highland Society intends to apply to His Majesty's Government for an extension of its charter. The charter of the English Society contains no authority to grant diplomas.

We have already said that a national diploma in agriculture appears to us as a desirable thing, if it could be granted by national authority and awarded only to thoroughly trained men. If powers to grant such a diploma are now being sought, the terms of the charter granted many years ago to the Highland Society supply some pertinent suggestions. If the diploma is to be really national, if it is to be stamped with a national authority, the schemes of education and examination laid down must not be decided on by the members of two agricultural societies. The charter of the Highland Society names six professors of the University of Edinburgh as members of the education committee. A charter granted with a similar object now would naturally take a similar line, but it would not limit itself to the University of Edinburgh. The *ex officio* members of a national committee should clearly include professors from other British Universities, and representatives of the Government Boards of Agriculture and Education. Until such a general body is constituted and authorised to grant diplomas, it is a misuse of language to speak of a national diploma in agriculture or dairying.

We turn now to the character of the examination at present held for the award of the so-called national diploma. If the diploma granted merely professed to be an agricultural societies' diploma, it would be scarcely necessary to speak on the subject; but the claim to national rank surely implies a diploma examination of first-rate quality, and if it fails of this it certainly demands public criticism.

The diploma in question is granted solely on the result of examinations, no previous course of training being required. The examinations for the diploma embrace many branches of elementary science; half of the subjects are taken by the candidate in his first year and half in his second year. The syllabuses published of the subjects for examination are undoubtedly meagre, some of them strikingly so. This is a real disadvantage, as the teachers who are preparing students for these examinations naturally limit their instructions to the syllabus. The examinations are both written and oral, but include no laboratory work. In each subject the written examination is limited to two hours, save in the case of practical agriculture to which three hours are allotted. The candidates are generally directed to attempt every question in the paper, six to ten questions being set. The whole of the subject of practical agriculture is dealt with in one paper of three hours, followed by an oral examination. The tests applied by the examiners would thus appear to be decidedly superficial. The number of marks allotted to each subject must be supposed to indicate their relative importance in the eyes of the examining board. We find that book-keeping and agricultural chemistry receive the same number of marks, while general chemistry and veterinary science each receive half as many marks as book-keeping! It is, indeed, essential that anyone who is to practise farming should pass an examination in book-keeping, but that a knowledge of agricultural chemistry should be taken to represent no greater previous study or no greater fitness for dealing with the problems of agriculture than a mastery of the art of posting trade accounts is certainly remarkable, and surely indicates a low appreciation of agricultural science by the examining board.

We have now done. The questions we have raised demand earnest attention. The character of our whole system of agricultural education depends on the standard set by what is apparently its highest grade. The present diploma has been given a title to which it has no right, and it has failed to justify by its excellence the rank which has been sought for it.

THE INTERNATIONAL CONGRESS FOR APPLIED CHEMISTRY.

THE fifth International Congress for Applied Chemistry, which sat in the Reichstags-Gebäude of Berlin from June 2 to 8 under the masterly presidency of Dr. Otto N. Witt, professor at the Technical High School of Charlottenburg, will be remembered as a great representative meeting. The actual attendance figure was not announced, probably because many of the members who had previously secured their tickets forgot to enter their names on arrival. But the figure cannot much fall short of 2700. Preparations had originally been made for 1500 members. About 2500 had arrived by the time of the opening of the Congress, and those joining later could not be favoured with invitations to the many pleasant receptions and excursions which had been arranged. Everything possible was, however, done by the local committee, over which Dr. J. E. Holtz presided, and by the general secretaries, Dr. Pulvermacher and T. Karwath. Everybody could gain admission to the grand "Commers." The Diet had made a grant of 15,000 marks, donations had poured in from many sides, and private hospitality was practised most liberally. Chemical works, in the strict sense of the word, were not opened to members, but visits to special exhibitions, scientific institutes, and manufactories would have supplied an amply long and instructive programme even if the sectional proceedings had left members far more spare time than they did. Some sections deliberated from 9 to 1, and again from 3 to 6 and later. The ladies were excellently taken care of during the whole congress week.

Though a more suitable and dignified place for the meeting could not have been found than the magnificent palace of the Imperial Diet, the large committee rooms of which afforded ample accommodation for all the sections, a parliament building is not a laboratory, and some of the sections had to emigrate for their experimental demonstrations. Section vii., fermentation and starch, sat mostly in the Institute for Fermentation, and had an exhibition of its own in the grounds adjoining this institute. Section ix., photochemistry, was isolated—and rather neglected, too—in the Technical High School at Charlottenburg. Section x., electrochemistry and physical chemistry, found a home in the Physical Institute of the University, close to the Reichstag. Each section had its official luncheon restaurant. The plenary meetings took place in the large hall of the Reichstag.

On Tuesday evening, June 2, President Witt welcomed the members in German, French, and English. The formal opening meeting on the next morning, at which Prince Frederick Henry represented the Emperor, was addressed by Prof. Witt; Secretary of State Count Posadowsky-Wehner, on behalf of the Empire; the Prussian Minister of Education, Dr. Studt; Mayor Dr. Reicke, on behalf of the City of Berlin; representatives of the learned and technical bodies which had taken part in the organisation; and the official delegates, Dr. Tilden speaking for Great Britain. As thirty Governments had sent delegates, the representative of Switzerland, Prof. Lunge, was heard as speaker for the minor States. There was a beautiful passage in President Witt's eloquent welcome: The flames of special research burn in the many chapels, and the Congress unites all the worshippers of the one universal science. Mayor Reicke also earned warm applause. The honorary president of the Congress, the veteran chemist Prof. Clemens Winkler, was not well enough to attend. The vice-presidents were Drs. H. Böttinger, M Delbrück, C. von Martius, E. A. Merck. The honorary vice-presidents, Moissan, Meldola, Piutti, and Christomanos, were appointed by acclamation.

The second plenary meeting on Friday morning was devoted to lectures. H. Moissan demonstrated some of the properties of the alkali hydrides which he has recently prepared. Potassium hydride is a snowy mass, which has to be kept in sealed tubes, and decomposes, when heated, into potassium and hydrogen; a tube was broken under water to exemplify this. Carbonic acid gas decomposes the mass, but the decomposition does not occur in the second of two tubes joined in series, because the presence of a trace of moisture in the CO_2 is necessary, nor does it occur below $-65°$ C. The KH_2 does not conduct the electric current, not even when fused, and the hydrogen in these alloys does not behave like a metal any more than it resembles metal in its liquid state.

Sir William Crookes then gave his discourse on modern views on matter: the realisation of a dream, dealing with speculations which the mysterious radioactive emanations suggest or support, and alluding to a fatal atomic dissociation which works when we brush a piece of glass with silk, and in sunshine and raindrops, in lightning and flames; protyle the formless mist, might once more reign supreme.

J. H. van 't Hoff then explained how the phase-law of Willard Gibbs enables us to understand the formation of natural salt deposits, referring to the influence of temperature, pressure, and time; the higher the basicity of the acid and the valency of the metal, the longer can a state of supersaturation exist, and when we have dibasic acids and bivalent metals, the addition of a solid crystal of the respective salt will no longer produce the crystallisation which is instantaneous in the case of Glauber salt.

The retrospective view of the ammonia-soda process, by E. Solvay (Brussels), did not enter into any detail. In the next lecture, on auto-oxidation, Carl Engler (Karlsruhe) went in a certain measure back to Schönbein's ozone and antozone. Oxygen does not appear to combine in single atoms, but always as a whole molecule, giving an unsaturated compound which yields a peroxide; this peroxide then, by giving off half of its oxygen, forms oxides, and we may distinguish two classes of bodies in this respect. The auto-oxidators bind the oxygen to peroxide and pass half of it on to the acceptor, which itself cannot bind the atmospheric oxygen. We have thus, in the animal and vegetable kingdoms, to which these arguments particularly apply, peculiar catalytic processes. Engler made reference to a paper, read by L. Woehler (Karlsruhe), who has extracted 18 per cent. of Pt from spongy platinum by hydrochloric acid, precipitated a protohydrate from the solution, and oxidised platinum, both as foil and sponge, by heating it in oxygen; a piece of foil absorbed 1·9 per cent. of oxygen in thirty-seven days.

The last general lecture was given by G. Kraemer, of Berlin, on coal tar researches.

The concluding plenary meeting had to pass or reject the sectional resolutions which are to be presented to the permanent committee of the International Congresses for Applied Chemistry, and also to select the place for the next meeting. Most of the numerous resolutions, concerning the drawing up of analytical reports, the undesirability of characterising reagents simply as pure, the specialisation of the Trauzl test (explosions within lead chambers), the transport of explosives, a uniform method of compiling statistics of accidents, the soda test of petroleum, the prohibition of additions of starch to press yeast, and other points were approved of without discussion. The electrochemical units, recommended by Nernst, Warburg, and Strecker, on behalf of the Bunsen Gesellschaft, the Physical Society, and the Elektrotechnische Verein of Berlin, for general use in publications, were adopted by the Congress, with an amendment by A. A. Noyes (Boston) that a committee of the Bunsen Gesellschaft should cooperate with other societies in order to make the system more comprehensive. The proposals of Section xi., legal and economical questions, however, met with opposition. It was not unreasonably complained that the resolutions were not in print before the meeting, though they had been published in the daily journals—not always in their final versions, however—and the meeting declined to sanction: that the registration as trade marks of words is not to be considered illegal for the reason that those words had previously been used in a definite sense. The assembly agreed to the general prohibition of white phosphorus matches, and recommended proper care of the employés in chemical works as a moral obligation the observance of which would serve the manufacturer's own interest. The two International Commissions, for analysis (created in 1900, chairman, Prof. Lunge) and for manures and fodders (created in 1898, chairman, Dr. von Grueber, of Malmö) were reappointed. The sugar chemists wished to settle their analytical methods for themselves. A new commission is to be elected for compiling a codex alimentarius.

The remarkable skill, tact, and firmness with which President Witt guided the assembly in these discussions were again called into requisition when the place of the next meeting was to be decided. On behalf of the Italian Government, the City of Rome, and the learned societies of Italy, Prof. Paterno di Sessa invited the congress to Rome. In accordance with a resolution unanimously passed by the British members of the Congress in a special meeting, at which thirty-eight members were present, Mr. I. Levinstein, president of the Society of Chemical Industry, asked the Congress to come to London in 1906, on behalf of that society and other societies interested; Dr. Tilden, the British delegate, supported the invitation. Both Italy and Great Britain had previously offered hospitality to the Congress, Italy, it would appear, twice, England once. The question was finally decided by a regular division, after the manner of the German Reichstag, when 294 members voted for Rome and 274 for London.

The sectional proceedings were conducted on the lines of the German Naturforscher-Versammlung. The presidents of the eleven sections and four subsections were almost all Berlin men. Their names

are:—(1) Analytical chemistry, G. von Knorre; (2) inorganic chemical products, A. Heinecke, director of the Berlin porcelain manufacture; (3*a*) mining and metallurgy, G. Weeren; (3*b*) explosives, W. Will; (4*a*) organic products (including tar), H. Wichelhaus; (4*b*) dyes, A. Lehne; (5) sugar, A. Herzfeld; (6) fermentation and starch, M. Delbrück; (7) agricultural chemistry, O. Kellner; (8) Hygiene, E. A. Merck; subsections (*a*) foods, K. von Buchka; (*b*) pharmacy, H. Thoms; (*c*) hygiene, M. Rubner; (9) photochemistry, A. Miethe; (10) electro- and physical chemistry, H. Böttinger (of Elberfeld); (11) legal and economical questions, C. A. von Martius. Before adjourning each day, the sections, however, nominated the president and vice-presidents for the following meeting. As a result, the time limits, twenty minutes for the reading of a paper, five minutes for each speaker, were not well adhered to. Each speaker is at once presented with a slip of paper on which he is to condense his remarks for publication in the daily journal or later in the reports. Some sections gave brief abstracts of the proceedings in the daily journals, others merely stated titles of papers and names of authors and speakers. A not inconsiderable number of the 457 reports and papers announced were not read owing to the—frequently only momentary—absence of the authors. Brief abstracts of some of the most important papers will follow.

H. BORNS.

NOTES.

THE annual conversazione, or ladies' soirée, of the Royal Society will be held on Friday, June 19.

PROF. J. J. THOMSON has had the honorary degree of doctor of science conferred upon him by the Columbia University, New York.

SIR OLIVER LODGE delivered the Romanes lecture in the Sheldonian Theatre, Oxford, on Friday last, on the subject of "Modern Views of Matter."

A GENERAL meeting of the Institution of Mining Engineers will be held in London on Thursday, July 2, and the following day in the rooms of the Geological Society.

MR. E. T. WHITTAKER, of Trinity College, Cambridge, will deliver an address before the Mathematical Society of University College, London, on Thursday, June 25, at 5.30 p.m., on "Some Present Aims and Prospects of Mathematical Research."

THE *Moniteur Officiel du Commerce* of Paris announces that an International Exhibition of the Industrial Appliances of Alcohol will be held at Rio de Janeiro in August.

A REUTER telegram from Cape Town states that the *Gauss* expedition has disproved the existence of Termination Island, which is marked on maps, the expedition passing over the alleged site of the island.

THAT the Soufrière in St. Vincent is still in a state of slight agitation is recorded by Dr. E. O. Hovey (*Sentry*, Kingstown, March 13). Outbursts issue from time to time from the centre of the lake in the crater. The most impressive changes which have taken place are in the erosion of the lately-erupted volcanic material, and he estimates that twenty-five million tons have been carried to sea from the valley of the Wallibou.

WE referred last week to the demonstration of the practical working of the Marconi long-distance wireless telegraphy given by Prof. Fleming during his lecture at the Royal Institution. Prof. Fleming has written to the *Times* complaining that the experiments were made particularly difficult to carry out towards the end of the lecture as the signals were being wilfully interfered with by an outside source. Mr. Nevil Maskelyne, in a reply to Prof. Fleming's letter, admits that he was the author of the interference, which was designed to demonstrate that the Marconi Company was not justified in its claim that it had solved the question of interference. A lecture at the Royal Institution scarcely seems a suitable occasion for settling commercial or semi-scientific disputes, nor can the result of the experiment be regarded as convincing. It shows, no doubt, that it is possible for an outsider to interrupt the signalling, but then it is also possible to throw stones at telegraph wires and break them; it does not demonstrate that two different systems working legitimately side by side would interfere with one another when the ordinary precautions necessary in commercial work were being taken.

LAST week telephonic communication was opened between London and Brussels. The line is particularly interesting, as the submarine portion forms the longest submarine telephone cable yet laid. The total length from St. Margaret's Bay (Dover) to La Panne, Belgium, is a little more than forty-seven miles; this is rather more than double the length of the Dover-Calais cable (twenty-three miles), which forms part of the London-Paris telephone line. The cable was made by Henley's Telegraph Works, and was laid in three sections by the *Alert* and the *Monarch*, the two joints being made at sea. The *Alert* laid 16½ miles of cable, chiefly in the shallow water off the Belgian coast, the remaining 30½ miles being laid by the *Monarch*; the cable crosses one of the Anglo-Belgian telegraph cables in deep water at about one-third of the total distance from La Panne. The length of the whole line from London to Brussels is 210 miles, made up as follows:—83 miles overhead lines in England, 80 miles overhead lines in Belgium, and 47 miles submarine cable.

THE promoters of the mono-rail high speed electric railway between Liverpool and Manchester hope to be able to start the work of construction this summer. When the railway is completed, a service of trains running at 110 miles an hour will be started; this will reduce the time taken over the journey from Liverpool to Manchester from forty to twenty minutes. Those interested in the scheme regard it as being the prelude to a reorganisation of express railway service throughout the country, and believe that once the possibility of working at these high speeds has been clearly demonstrated, the railway companies will be induced to build special mono-rail tracks alongside their existing lines for express services. It is already rumoured that the Great Western Railway is considering the advisability of constructing such a track for an express service between Bristol and London. In connection with high speed traction on railways, the experiments to be carried out in Germany during the next few weeks will be watched with interest. All the leading locomotive builders and electrical firms have been invited to submit designs, and trials will be made on the lines between Hamburg, Hanover and Berlin; it is hoped to attain speeds of 90 to 100 miles an hour with safety.

MR. A. MEEK informs us that a full-grown male beluga (*Delphinapterus leucas*) came ashore at the mouth of the Tyne on June 10, and was captured by the salmon fishermen. It measured 14 feet 2 inches. The specimen has already been cut up by the purchasers, so that it was possible to see that the teeth numbered eight on each side of each jaw, or thirty-two altogether, and that there were

eleven ribs on each side. The skeleton is to be presented to the Hancock Museum or to the Durham College of Science. Mr. Meek states that, so far as he is aware, an example of this species has not before been caught south of the Forth.

THE establishment of an economic tripos in the University of Cambridge will mark an important step in the movement which it is to be hoped will ultimately break down the barrier at present existing between the university man and the man of business. The proposed tripos has been warmly approved by a number of leading representatives of the railway, ship-owning, financial, mercantile, and manufacturing interests, as well as by prominent members of the Government. The tripos as proposed will consist of two parts, of which the first is to be taken in the second year, and will not qualify for a degree except in conjunction with some other examination. The syllabus of the first part includes (1) an essay paper; (2) one paper on the existing British Constitution; (3) two papers on recent economic and general history; (4) three papers on the general principles of economics. The historical part leads up to part ii., where specialisation is encouraged. In both parts questions, not all of which are optional, may be set, including quotations from French or German writers, so that a knowledge of these languages is essential. Among the careers for which the proposed tripos will afford a valuable training are those of the country squire, the politician, the business man, and the administrator of charities. It is only by the study of the principles of economics and political science treated as exact sciences, but founded upon actual facts of business life, that our country can hold its own against the competition of other countries where these principles are so studied, and can thus maintain that supremacy which it was able to obtain under entirely different conditions by rule of thumb methods and by pure speculation.

THERE was little new in the narrative of the British Antarctic Expedition given by Sir Clements Markham at a special meeting of the Royal Geographical Society on June 10. Commander Scott's short record of the voyage of the *Discovery* and work of the expedition, brought back by the relief ship *Morning* at the end of last March, and printed in NATURE of April 2 (vol. lvii. p. 516), contained the substance of what has been achieved. Some of the results of explorations were summarised in a subsequent number (p. 12). The paper read by Sir Clements Markham confirmed the information given in these two messages. The description and discussion of the scientific results are left until Commander Scott and his fellow-explorers return to this country with details of their work. In proceeding along the ice-barrier, the furthest easterly point reached was 152° 30′ W., and at this extremity extensive land, to which the name King Edward VII. land has been given, was found, rising to heights of 2000 to 3000 feet. The ice-barrier was studied from this point to Cape Crozier, and its height was found to vary from 30 to 900 feet. The winter quarters of the ship were in lat. 77° 50′ S., which is more than 500 miles further south than any ship has wintered before. Meteorological observations made in this position over a period of two years will be of great value. The most southerly point reached by a sledge journey from the ship was lat. 82° 17′ S., long. 163° E., and from it a range of mountains was seen extending as far as visible in a south by east direction. The journey during which these observations were made occupied ninety-four days, and the explorers must have travelled more than 980 statute miles. Another journey was made to the west of the ship, the farthest point reached being in lat. 77° 21′ S., long. 157° 25′ E. The horizon to the west of this point was unbroken and clear. An altitude of 9000 feet was attained at a distance of 142 miles from the ship as the crow flies. Many interesting photographs were shown at the meeting, and judging from them and the brief messages brought back by the *Morning*, the expedition will contribute much to our knowledge of the physical and biological conditions of South Polar regions.

A SHORT account of one of the sections of the International Congress of History was given in NATURE of April 30 (vol. lxvii. p. 613). A memoir by Prof. Ernest Lebon, describing a plan for an analytical bibliography of contemporary works on the history of astronomy, was among the papers presented to the congress, and has since been laid before the Paris Academy of Sciences. At the meeting of the Academy at which the memoir was received, M. Paul Appell, Dean of the Faculty of Sciences of the University of Paris, spoke in favour of Prof. Lebon's plan, and said that the bibliography would not only be valuable to scientific historians, but would also be welcomed by all astronomers. The May number of the *Bulletin de la Société astronomique de France* contains the titles of the chapters of Prof. Lebon's work, and the names of the authors of books and papers which are summarised in it.

DURING a heavy thunderstorm at Heppner, Oregon, on Sunday last, a remarkable downpour of rain occurred, producing a destructive flood, which caused the death of more than three hundred people. Heppner is situated in a gulch through which a stream runs usually only a few feet in width. On Sunday a dense cloud suddenly covered the mountain overlooking the town, and the rain which followed produced a great mass of water which rushed down the mountain and carried everything before it, the little stream being quickly converted into a deep torrent about four hundred feet wide. The flood swept a clean path more than a mile long and two blocks wide through the town.

THE daily weather report issued by the Meteorological Office on Saturday morning, June 13, showed that the area of high barometric pressure lying outside our Atlantic coasts had to some extent given place to a disturbance of a very complex character which occupied the whole of England. By about midday heavy rain set in over a great part of the country, and continued persistently, especially over the southern districts, during the following days. In the neighbourhood of the metropolis rain continued with scarcely any intermission for a period of 59 hours, and the amount measured in the week was 4·82 inches, being nearly 3 inches in excess of the average for the month. In the north of London the fall was even heavier than in the south, and amounted to about 2¼ inches in the 24 hours ending 8h. a.m. on Monday, while the temperature, owing to the continuation of northerly winds, was about 20° below the average. To find such a heavy fall of rain in June we have to go back to 1860, when an amount of 5·8 inches was measured at Greenwich, but this was spread over twenty-three days. The average rainfall for the neighbourhood of London is 1·93 inches only for the month of June. The heavy rainfall was entirely due to the lingering of the low barometric pressure to the southward.

IN the *Quarterly Journal* of the Royal Meteorological Society for April last, Mr. W. Marriott contributed an interesting paper on the earliest *telegraphic* daily meteorological reports and weather maps. The paper refers specially to reports relating to this country, although mention is made of the maps compiled in the United States

by the Smithsonian Institution by means of telegraphic reports, in 1849, and some years previously, from monthly returns, by Prof. Espy. The first telegraphic weather report in this country appears to be that published by the *Daily News* on August 31, 1848. The first printed daily weather map was that issued in August, 1851, at the great exhibition in Hyde Park. The first Government daily weather report was prepared by Admiral FitzRoy, and issued to London newspapers in 1860. In January, 1871, the *Shipping and Mercantile Gazette* published daily wind charts, prepared by the Meteorological Office, and in March, 1872, that office issued its first daily weather maps. The 6h. p.m. weather maps published by the *Times*, and prepared by the Meteorological Office, commenced on April 1, 1875. As Mr. Marriott has also quoted the weather maps prepared by Mr. Glaisher from July, 1849, which do not appear to have been entirely based on telegraphic reports, we may direct attention to one or two early English investigations of a somewhat similar nature. In the report of the Meteorological Department of the Board of Trade for the year 1857, Admiral FitzRoy directed attention to the desirability of collecting synchronous weather observations, and subsequently some hundreds of synchronous charts were prepared in the office, although not published, excepting for the time of the "Royal Charter" storm (October, 1859). Mr. Francis Galton discussed the daily weather for the month of December, 1861, and some 600 maps and diagrams were published in "Meteorographica" (Macmillan, 1862). With respect to work abroad, it may not be out of place to state that between 1816–20 H. W. Brandes apparently prepared synchronous weather charts for each day of the year 1783, from the Mannheim and other observations. Although the charts were not published, the data on which they were constructed were quoted in his "Beiträge zur Witterungskunde" (Leipzig, 1820), and one of the maps (for March 6, 1783) was reconstructed and published in "Les Bases de la Météorologie dynamique," by Dr. Hildebrandsson and M. Teisserenc de Bort (Paris, 1898).

AT the recent flower show held in the Temple grounds, amongst the hardy shrubs there was displayed a profusion of maples, many of which hail from Japan. An interesting article on these and other Japanese trees which commend themselves by reason of their quick growth and free flowering habit is contributed by Mr. J. H. Veitch to the last number of the *Journal* of the Royal Horticultural Society. Amongst the more technical contributions to be found in the same publication, one of considerable importance is the account of manurial experiments with vegetable crops carried out by Dr. Dyer and Mr. Shrivell.

IN the absence of the director, the annual report for 1902 of the Royal Botanic Gardens, Ceylon, has been issued by the assistant director, Mr. J. B. Carruthers. During the year an estate of 500 acres was acquired with the object of turning it into an agricultural experiment station, and was placed under the charge of Mr. H. Wright. The value of a special establishment for dealing with agricultural matters of economic importance is evident, and the presence of aggravated canker amongst the cacao trees growing on the land acquired for the purpose provided an opportunity for demonstrating the scientific treatment of this disease. In the ornamental lake of the Peradeniya Gardens an artificial island was constructed of mud taken from a depth of 8 to 10 feet below the water. It is expected that an instructive object lesson in the seed dispersal of terrestrial plants will be afforded by the systematic examination of the plants which develop on this area. A first attempt to raise worms and silk cocoons in the island is recorded by Mr. E. E. Green. In spite of untoward circumstances, of which the principal was a shortage of mulberry leaves or any other efficient substitute, the few cocoons raised were quite satisfactory, and it seems probable that the industry might with advantage be taken up by the natives.

DR. HÄCKER, whose investigations on the cytology of Copepods are well known, has recently (*Jen. Zeitschr, f. Naturw.* 1902) reinvestigated the question as to the permanence of the maternal and paternal chromosomes in the germ cells of the offspring. The result has been not only to show that the parental chromosomes remain distinct in the nuclei of the germ tract of the young organisms, but that the processes associated with the "reduction-divisions" may prove to be even more complicated than had previously been supposed. It appears that in the early prophase of the heterotype mitosis, tetrads are formed in numbers equal to those of the *somatic* chromosomes. These are divided, during the first polar mitosis, by an "equal" division, twelve dyads travelling to the respective poles. These the dyads fuse longitudinally in pairs, thus giving rise to the reduced number (6) of chromosomes. The next mitosis divides these in such a way that the collaterally fused pairs are transversely split, and thus a true qualitative "reduction division" is brought about. It would thus appear that the first of the two divisions effects the mingling of the parental chromosomes, whilst the second ensures a qualitative distribution of those originating from the *penultimate* (grandparent) generation. This occurs in such a way that each of the six chromosomes ultimately passing to the daughter-nuclei consists of halves contributed by two different grandparents.

WE have received the report (Aarsberetning) of the Bergen Museum for 1902.

NO. xi. of the *Sitzungsberichte* of the Vienna Academy for the current year contains a *résumé* of the results of Dr. F. Steindachner's recent expedition to Brazil.

THE "dragonets" (Callionymidæ) and allied fishes of Japan are described by Messrs. Jordan and Fowler in No. 1305 of the *Proceedings* of the U.S. Nat. Museum, several new forms being recorded.

AMONG the contents of the June number of the *Entomologist* we find a paper on the parasitic Hymenoptera and Tenthredinidæ collected by Mr. Whymper in the Andes of Ecuador, and a continuation of Miss Sharpe's list of butterflies from British East Africa.

THE *Proceedings* of the South London Entomological and Natural History Society for 1902 is illustrated by two plates, devoted to the life-history of the crustacean *Argulus foliaceus*, which lives parasitically on sticklebacks. The council reports that the affairs of the Society continue to prosper, the number of members again showing a slight increase.

A REVISION of the American moths of the family Gelechiidæ, with descriptions of new species, by Mr. A. Busck, of the Department of Agriculture, appears in vol. xxv. (No. 1304) of the *Proceedings* of the U.S. Nat. Museum. No. 52 of the *Bulletin* of the U.S. Nat. Museum, comprising 723 pp., is devoted to a list of North American Lepidoptera, which will doubtless prove of great value to entomologists.

IN their thirty-first annual report (for 1902) the directors of the Zoological Society of Philadelphia record a general satisfactory progress on the part of that institution. With the exception of a slight diminution, probably due to un-

favourable weather, during three months, the number of admissions to the gardens shows a steady increase throughout the year. A number of species of animals have been exhibited for the first time in the menagerie during the year.

"SAWDUST AND FISH LIFE" is the title of an article in a recent issue of the *Transactions* of the Canadian Institute. From the result of experiments in aquariums, the author, Dr. A. P. Knight, gives reasons for the belief that the sawdust thrown in large quantities into the Canadian rivers is very harmful to fish; but from actual observations in the rivers themselves, it does not appear that the destruction is as great as might have been expected.

WE have received a copy of an "Outline of Special Course in Natural History for Training Colleges and King's Students," just issued by the Marischal College, Aberdeen. It contains outlines for demonstrations on classification, the adaptation of animals to their surroundings, and examples of the leading types of animal life, concluding with suggestions for seasonal studies in natural history. Although the illustrations are somewhat crude, the pamphlet seems well adapted to its purpose.

THE Liverpool Marine Biology Committee is to be congratulated on the issue of the tenth fasciculus of the well-known "L.M.B.C. Memoirs," this part, of which Prof. J. R. A. Davis and Mr. H. J. Fleure are the joint editors, being devoted to the common limpet (Patella). The mode of treatment of the subject follows the line of the earlier issues, and the illustrations are numerous. The authors believe that, although limpets are rightly included among the lower gastropods, yet that they form an isolated type, which has been specialised in connection with their adoption of the habit of adhering to exposed surfaces, and making limited excursions for the purpose of feeding.

THE report on the examination of food, drugs and public water supplies reviewing the work of the Laboratory of Hygiene of the State of New Jersey, U.S.A., has reached us. It deals especially with the analytical methods employed in testing foods and drugs; these are detailed, and should be of considerable service to public analysts in this country.

WE have received the "Year Book" of the Livingstone College. The College trains missionaries in the elements of medicine and hygiene, the curriculum extending over a period of nine months. During this time the students are systematically trained in the elements of anatomy and in hygiene, nursing, cooking, &c., suitable to tropical climates, as well as in the prevention and treatment of the ailments they are likely to meet.

A COPY of the report of the Medical Officer of Health for the City of London for 1902 has been received. It contains an account of the procedures adopted by the Corporation of London for the sanitary protection of its citizens, some of which have already been noticed in these columns, *e.g.* the prohibition of spitting, and condemnation of typhoid-contaminated shell-fish. A point of interest is that, though the *day* population of the City probably exceeds 359,000, only 339 births were registered during 1902.

THE geology of the country near Leicester is the title of a memoir, by Mr. C. Fox-Strangways, lately issued by the Geological Survey. It is accompanied by a colour-printed map of the area, which includes Mount Sorrel and Leicester on the west, and parts of Rutlandshire on the east. Excepting for the granite quarries at Mount Sorrel, numerous brick-yards, sand and gravel pits, and occasional lime-works, the country is essentially one of meadow and pasture, and a famous hunting ground, the subsoil being for the most part clay—Boulder-clay, Lias-clay, Keuper Marl, and Alluvium. As most of the area is drift-covered, this new map differs very largely from the old series geological survey map, on which only the "solid" geology was depicted. In addition this new map has alongside it a colour-printed section which gives an excellent and instructive view of the structure of the ground. In the memoir Mr. Strangways gives full particulars of the strata, a catalogue of the fossils from the Trias and Lias of Leicestershire and Rutland, and numerous records of borings and well-sections. A photographic plate shows the weathered crags of granite at Mount Sorrel, grooved by the erosive power of wind-drifted sand in Triassic times, as pointed out by Prof. Watts. The price of the memoir is 3*s.*, and of the map 1*s.* 6*d.*

A "Subject List of Works on Architecture and Building Construction, in the Library of the Patent Office," has been published in the Patent Office library series. The subject list consists of two parts, viz. a general alphabet of subject headings, with entries in chronological order of the works arranged under these headings; and a key or summary of these headings shown in class order. Copies of the publication can be obtained at the Patent Office, Chancery Lane, W.C., price sixpence.

A SECOND revised edition of the "Smithsonian Physical Tables," prepared by Prof. Thomas Gray, has been published by the Smithsonian Institution. This edition differs from that issued in 1897 in a few particulars only, the chief alteration being that the table of electrochemical equivalents now contains columns showing atomic weights with O=16 and H=1 based upon the report of the International Committee on Atomic Weights. The table giving values of the density and volume of water between $-10°$ C. and $100°$ C. needs revision, the volumes from $46°$ to $100°$ being obviously wrong in the second decimal place. This, however, is a small point, and can be easily corrected by anyone using the tables. By issuing works of this kind, which are very valuable to teachers and investigators, but for which the demand is necessarily limited, the Smithsonian Institution is doing great service to science.

THE first number of the "Year Book" of the Carnegie Institution of Washington contains detailed information of what has already been accomplished for the encouragement of scientific research as the result of the munificence of Mr. Carnegie. Upwards of 38,000*l.* has been voted to assist a number of men of science in their investigations, but the fund, large as it is, has proved inadequate to meet all the requests for aid received by the trustees. As a consequence it has been found necessary to limit the activities of the institution—ground already occupied will be avoided, the systematic education of students will not be undertaken, and sites and buildings for other institutions will not be provided. It is to be understood, the "Year Book" states, that apparatus and materials purchased to assist investigators are to be regarded as the property of the Carnegie Institution. The persons assisted are expected to report upon the methods followed and the results obtained, and to state in the published results that aid was received from the Institution. Appropriations are to be made from time to time for the printing of papers of acknowledged importance To secure the counsel of experts, special advisers have been, and will be, invited from time to time for consultation. The first appendix, which runs to 238 pages of the "Year Book," consists of reports of eighteen advisory committees on the chief branches of scientific

knowledge. Another appendix deals with the proposed explorations and investigations on a large scale, and is contributed to by several well-known American men of science.

A STRIKING illustration of the enormous advance that has taken place in chemical manipulation during the past two or three years is afforded by a paper, in a recent number of the *Berichte*, on the "Evaporation and Boiling of Metals in Quartz-glass and in the Electric Furnace in the Vacuum of the Kathode-light." Dr. F. Krafft there states that the quartz tubes could be safely heated to 1200°, and with care up to 1400° C., even when exhausted to the low pressure required for the production of the kathode-light in a vacuum tube, and that even when containing metals they could be safely taken from the furnace at 1200°, allowed to cool in the air without annealing, and then replaced in the furnace without any risk of fracture. By using an electric furnace it was possible not only to regulate the temperature within 2° or 3° between 18° and 1400° C., but also to connect the quartz tubes to the pump by means of a ground-glass joint made tight with wax, the wax remaining unmelted although within a few inches of the hottest part of the furnace.

THE results achieved by the methods described in the foregoing note were remarkable. The only vapour in the quartz tube was that of the metal, which extended from the surface of the liquid to the top of the furnace, above which condensation took place. Under this almost inconceivably low pressure cadmium boiled at 420°, *i.e.* below the boiling point of sulphur, zinc at 545°, and bismuth below 1000°, the temperature of the furnace being about 150° above that of the boiling metal. Lead could be rapidly distilled with a furnace temperature of 1180°, and antimony at 775–780°. Silver began to evaporate fairly rapidly at 1200°, but did not boil at 1340°; copper showed a distinct, though slight, evaporation at 1315°, but gold, even at 1375°, the highest temperature reached in the experiments, gave only a small mirror of silver, and below it a tiny distillate of gold weighing less than 2 mg. It is of interest to note that the boiling points in an absolute vacuum of these metals, which probably lie at about 1400°, 1600°, and 1800° respectively, are in the order of increasing valency, and not in the order of their atomic weights.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*), a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. C. S. Birch; a Two-spotted Paradoxure (*Nandinia binotata*), two Senegal Touracous (*Turacus persa*) from West Africa, presented by Mr. James Drew; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by the Hon. Sibyl Edwards; a Patagonian Cavy (*Dolichotis patachonica*) from Patagonia, presented by Sir E. G. Loder; a Common Quail (*Coturnix communis*), British, presented by Mr. J. Woodward; an Adanson's Sternothere (*Sternothoerus adansoni*) from West Africa, a Pale Lizard (*Agama pallida*), an Egyptian Eryx (*Eryx jaculus*), a Blunt-nosed Snake (*Tarbophis obtusus*), a Schokari Sand Snake (*Psammophis schokari*), a Diademed Sand Snake (*Lytohynchus diadema*) from North Africa, presented by Captain Stanley Flower; a Stair's Monkey (*Cercopithecus stairsi*) from British East Africa, a Green Monkey (*Cercopithecus callitrichus*), an Eroded Cinixys (*Cinixys erosa*) from West Africa, a Black-headed Lemur (*Lemur brunneus*), a Grey Lemur (*Hapalemur griseus*) from Madagascar, five Grey Monitors (*Varanus griseus*), five Spiny-tailed Mastigures (*Uromastix acanthinurus*), eight Ocellated Sand Skinks, a Corais Snake (*Coluber corais*) from South America, a King Snake (*Coronella getula*), a Mocassin Snake (*Tropidonotus fasciatus*) from North America, a Carpet Python (*Python variegata*) from Queensland, a Rhesus Monkey (*Macacus rhesus*, var.), two Indian Rat Snakes (*Zamenis mucosa*) from India, deposited; a Burrhel Wild Sheep (*Ovis burrhel*), an Axis Deer (*Cervus axis*), born in the Gardens.

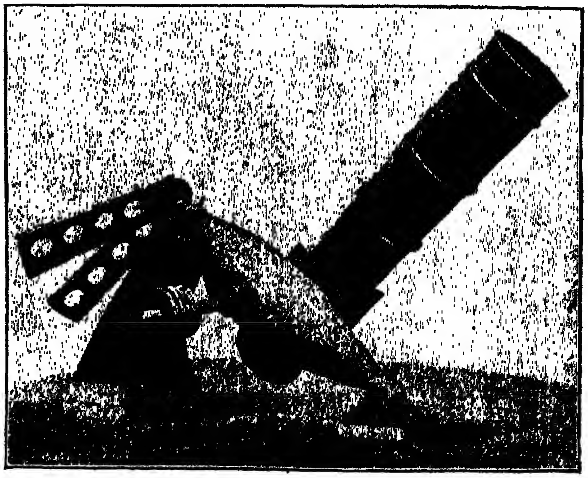
OUR ASTRONOMICAL COLUMN.

CONNECTION BETWEEN SUN-SPOTS AND ATMOSPHERIC TEMPERATURE.—M. Charles Nordmann has recently completed a discussion of the effect of sun-spots on the mean annual temperature of the earth's atmosphere in tropical regions. The period under discussion extends from 1870 to 1900, and the method of discussion is analogous to that published by Köppen in 1873, which dealt with the period 1830 to 1870.

M. Nordmann has compared the mean annual variations of temperature from the normal, as obtained from the observations made at thirteen tropical stations situated in various longitudes, with Wolf's numbers for sun-spot frequencies during the same period, and from the two curves obtained by plotting the two sets of numbers he has arrived at the following conclusion:—"The mean terrestrial temperature follows a period sensibly equal to that of solar spots; the effect of spots is to diminish the mean temperature, *i.e.* the curve which represents the variations of temperature is parallel to the inverse curve of sun-spot frequencies (*Comptes rendus*, No. 18).

THE CROSSLEY REFLECTOR OF THE LICK OBSERVATORY.—This reflector, it will be remembered, was presented to the Lick Observatory by Mr. Crossley, of Halifax, Yorks, and contains one of the splendid mirrors made by the late Dr. Common. It has an aperture of 3 feet, and a focal length of 17 feet 6 inches. When remounted and used at Lick it was found that the instrument was unsuitable for long exposures on account of flexure and other defects, therefore a new mounting has been devised and constructed by Messrs. Harron, Rickard and McCune, of San Francisco, and is found to work satisfactorily.

The polar axis is 14 feet long, and is so raised as to allow the instrument to be used in all positions. As shown in the accompanying illustration, this axis rests on two piers, the northern one consisting of an inclined steel



pillar, 8 feet high, resting on a concrete and brick foundation which is 6 feet high, whilst the bearing for the southern end, carrying the altitude and azimuth adjustments, rests directly on the brick and concrete foundation, the downward thrust being borne by hardened steel balls. The telescope tube is carried by the strong steel declination axis, and the mirror is contained by a cast-iron cell in the lower cylindrical section of the steel tube, whilst the photographic plate holder, with the usual adjustments, is placed

at the focus of the mirror and in the optical axis of the same.

The driving motion of the clock is transmitted to the telescope by two sectors, one of which is being run back ready to be put into gear again whilst the other is being used; each sector allows of one hour's exposure being made. The "following" is performed by means of an auxiliary telescope rigidly attached to the plate holder (*Scientific American*, May 16).

THE RELATIONSHIPS BETWEEN ARC AND SPARK SPECTRA.—In No. 4, vol. xvii. of the *Astrophysical Journal* there appears an advance translation, by the author, of a paper on the above subject recently communicated to the K. Akademie der Wiss. zu Berlin by Prof. J. Hartmann.

In his experiments on the arc spectrum of magnesium, using metallic poles, he found that the line at λ 4481, which is generally regarded as essentially a "spark" line, appears in the arc spectrum, and actually increases in intensity as the current strength becomes *less*: this is plainly shown in a table which accompanies the paper. From this and similar results the author arrives at the conclusion that the *higher* temperature of the spark, as compared with that of the arc, is open to question.

Further experiments showed that a high voltage was not necessary for the production of "spark" lines in the arc, for when a current of 20 volts and 4 amperes was used the line 4481 was about thirty times more intense than when 120 volts and 4 amperes were used.

Prof. Hartmann arrives at the conclusion that the energy of the electric discharge and of the chemical changes may play a more important part in the production of "spark" lines than temperature does, and in his experiments, in which the arc was formed in an atmosphere of hydrogen, he has shown that the dielectric is also an important factor in determining the nature of the spectrum obtained.

RADIO-ACTIVE PROCESSES.[1]

THERE are three distinct types of radiation spontaneously emitted from radio-active bodies, which may be called the α, β, and γ rays. The α-rays are prominent in causing the conductivity of a gas, they are easily absorbed by metals, and are projected bodies, not waves. These bodies are about the size of a hydrogen atom, they are positively charged, and travel with about one-tenth of the velocity of light. The β-rays are similar in all respects to the kathode rays produced in a vacuum-tube. The γ-rays are probably like Röntgen rays, but of very great penetrating power. The α-rays are by far the most important. In addition to these rays two of the radio-elements give off radio-active "emanations," which are in all respects like gases. The radiations from these emanations are not permanent, but fall off in a geometrical progression with the time. The radiation of the thorium emanation falls to half value in one minute, that from radium in four days. They have all the properties of gaseous matter in infinitesimal quantity. Their coefficients of diffusion can be measured, the order of their molecular weights is 100, they are occluded by solid compounds producing them, and may be condensed at low temperatures. The radium emanation condenses sharply at $-150°$ C., the thorium emanation between $-120°$ C. and $-150°$ C. The two emanations excite on objects with which they come in contact two kinds of temporary radio-activity, that from the radium emanation decaying much faster than that from the thorium emanation. The latter decays in a G.P. with the time falling to half value in eleven hours. These effects appear to be produced by solid matter in invisible and unweighable quantity, which can be dissolved off in some acids but not in others. On evaporating the solutions, the radio-activity is obtained unchanged in the residue. The experiments of Crookes and Becquerel in separating by chemical treatment the matter responsible for the activity of uranium, called uranium X, were referred to, together with the latter's observation that the separated activity had completely decayed after the lapse of a year, by which time the uranium itself had completely recovered its activity. The work of Rutherford and Soddy on thorium was then discussed in detail. Thorium precipitated in solution by ammonia retains only 25 per cent. of its activity. If the solution is evaporated and ignited the remaining 75 per cent. is found in the extremely small residue left, which by reason of its separation is different chemically from thorium, and was called thorium X. Left to themselves, the thorium gradually recovers its activity, and the ThX loses it. The activity of the latter falls in a G.P. with the time, the half value being reached after four days. At any time the sum total of the two activities is a constant. This would occur if the ThX were being continually produced by the thorium, and this was shown to be the case by precipitating thorium at definite intervals after its separation from ThX. The ThX, and not thorium, produces the thorium emanation. The production of ThX by thorium, of the emanation by ThX, and of the matter causing the excited activity by the emanation, are all changes of the same type, although the rates of change are distinct in each case. The change of uranium into uranium X is also similar, being the slowest of all. Twenty-two days elapse before uranium freed from ThX recovers one-half of its activity. In radium the radium emanation is the first product produced, and since this in a solid is almost completely occluded, the activity of a radium salt after it has been obtained from its solution rises after precipitation to several times its original value, due to the occlusion of the emanation. In all three radio-elements a part of the radio-activity is non-separable, and this part consists only of α-rays. The β-rays only result at the last stages of the process that can be experimentally traced. In all cases the radiation, from any type of active matter, is a measure of the amount of the next type produced. Thus the radio-activity of ThX at any period throughout its life is always a measure of the amount of emanation it produces. These results find their explanation if it is supposed that the α-particles projected form integral portions of the atom of the radio-active element. Thus ThX is thorium minus one or more projected α-particles. The emanation similarly is ThX less a further α-particle, and so on. The non-separable activity is due to the atoms of the original radio-element disintegrating at a constant rate. The whole of the processes take place unaltered in velocity, apparently under all conditions of temperature, state of aggregation, and chemical combination. This is to be expected of a subatomic change in which one system only is involved at each change. On this view the spontaneous heat-emission of solid radium salts, discovered by Curie, is explained by the internal bombardment by the α-particles shot off and absorbed in the mass of the substance. The amount of energy given out in these subatomic changes is enormous, and from Curie's experiments it can be deduced that each gram of radium gives out 10^9 gram-calories during its life, which is sufficient to raise 500 tons a mile high. It seems probable that the internal energy of atoms in general is of a similar high order of magnitude.

[1] Abstract of paper read before the Physical Society on June 5, by Prof. E. Rutherford, F.R.S.

SOME UNSOLVED PROBLEMS IN ENGINEERING.[1]

THE present lecture is devoted to the indication of some of the directions in which the further aid of the physicist is more immediately required by the engineer, while it is hoped that in future lectures each branch of inquiry thus pointed out will be dealt with in detail by someone who has made that particular subject his special study.

In view of the great interests—monetary and otherwise—involved, it appears to me that the whole question of steam-jacketing, and particularly the application of such jackets to compound or multiple-expansion engines of modern types and of large power, using steam at high pressures, deserves a much more thorough and systematic investigation than it has hitherto received.

The action of steam-jackets is, however, only one of several important problems relating to steam-engine economy at present remaining unsolved. Another is the

[1] Abridged from the eleventh "James Forrest" lecture delivered by Mr. W. H. Maw to an Engineering Conference on June 16, at the Institution of Civil Engineers.

economic effect of interheaters, through which the steam is passed on its way from one cylinder to another, of a compound or triple-expansion engine. During the past half-century, numerous types of interheaters have been designed and applied more or less spasmodically; while, in recent years, the use of such appliances has become a prominent feature in certain branches of American practice. The data on which the use of such heaters is founded, however, are far from being of a satisfying character, and they present discrepancies which certainly require clearing up.

What is really required is accurate information as to the extent to which our most advanced steam-engine practice can—especially in the case of large power units—be improved by the use of superheated steam, and as to the manner in which such improvement can best be realised. In connection with this matter, I may point out that we are much in want of a thorough determination of the physical properties of superheated steam, extending over the range of temperatures and pressures likely to be employed in practice. Such a determination may, I hope, soon be undertaken. Equally desirable also is the thorough investigation of the action of steam—both saturated and superheated—in the various types of turbine motors, a matter which has, as yet, been by no means dealt with so exhaustively as its great, and rapidly growing, practical importance deserves, and respecting which many lessons undoubtedly remain to be learnt.

In addition to the various points already mentioned, the question of the economy to be secured by the use of still higher pressures of steam than are now used requires investigation. We are without any direct determination of the latent heat, volume, and temperature corresponding to pressure in the case of steam of pressures exceeding 350 lbs. per square inch. The published data relating to steam of higher pressures have been obtained by extrapolation, and are by no means strictly to be relied upon.

The thorough investigation of the theory and practical working of internal-combustion engines presents for solution problems at once so numerous and so varied as to tax to the utmost the skill and ingenuity of the experimenter. There appears to be good ground for believing that with an increase of temperature there is a very substantial increase in the specific heats of such gases. While, however, the general fact may be regarded as proved, the numerical data necessary to enable that conclusion to be turned to practical account are far from having been fixed with certainty, and further determinations are greatly wanted.

The value of experiments on internal-combustion engines depends in a most important degree upon the accuracy with which variations of temperature can be observed, both in the cylinder before and during explosion, and in the walls of the chamber in which the explosion occurs. As Prof. Callendar has pointed out, the temperature assumed by the platinum wire of an electric resistance thermometer exposed to such gases must necessarily be less than that of the gases themselves. Moreover, the rate at which heat is communicated from the gases to the wire is dependent not only upon the difference of temperature, but also on the pressure, in a way not yet accurately known; and thus the accurate determination of the results of explosions in internal-combustion engines means not merely the skilful use of known appliances, but the determination of certain physical constants involving much expenditure of time and labour. Then, again, the effect of the injection of water or water-vapour into the cylinder in itself offers much scope for investigation, as does also the influence of the quality and quantity of the lubricating oils on the gaseous mixture. The governing of internal-combustion engines and the regulation of the powers developed by them at various speeds and under varying conditions are also matters which present many unsolved problems.

In the case of large bridges, roofs, and structural work of that class, there is ample scope for aid to be given by the better determination of the amount and effect of wind-pressure—a branch of experimental inquiry which is at present far from being in a satisfactory state. What is greatly required is a thorough investigation of the action of the wind on surfaces of different areas and shapes, and particularly its effect on partially shielded areas. Amongst other points requiring settlement is the action of wind on the lee-side of roofs—a matter on which the experiments of Irminger have thrown much light, but which still requires further investigation.

In the determination of the stresses induced in the elements of a structure by the forces applied to that structure, there still remain many problems of importance imperfectly solved. The theory of the plate-web girder, for instance, is in a far from satisfactory state, particularly as regards the action of web stiffeners, the stresses on the web itself, and those on the connections between the web and the flanges. The whole subject of resistance to compound stresses—such, for instance, as those existing in the web of a plate girder or a flat stayed plate, forming part of a steam boiler—is one urgently requiring further experimental investigation.

Then, again, we are now largely using hollow shafts for marine and other purposes, and the relation of these to solid shafts of the same nominal strength, as regards the power of resisting repetitions of varying or alternating stress, has not yet been systematically investigated. Another point is the effect of oil-tempering and different modes of annealing on the endurance of fatigue, a matter which, in view of the effect of similar treatments on the ultimate strength and limit of elasticity of steel, is one of much importance.

The great problem we have still to face—and it is a problem which will tax to the utmost our powers of research—is the determination of what the change which we call elastic fatigue really is. The indications of ordinary testing machines do not reveal any change in the behaviour of a material which has certainly exhausted a large proportion of its "life" under repeated applications of stress, and we must evidently, to solve the problem, have recourse to other modes of inquiry. What is the change of structure produced by fatigue, and in the case of any but pure metals is this change accompanied by any rearrangement of the constituents? How is this change of structure affected by variations of treatments, by annealing, or, in the case of steel, by tempering?

It is sometimes of considerable importance to ascertain whether a certain object, as, for instance, a propeller shaft, or a portion of a bridge structure, or a steel rail, has or has not been injured by the repeated applications of stress to which it has been subjected; and at present the only method of determining this is the testing to destruction of the object respecting which the information is desired. But if we knew accurately in what part of the object the stresses to which it had been subjected would first cause injury, and if we further knew in what way the existence of such injury would be indicated by change of structure, it would follow that the microscopic examination of a small portion, cut from the most sensitive part of the object, would afford a valuable indication of what was going on.

There are other questions which appeal directly to the users of steel. Amongst such questions are the oil-tempering of mild steel forgings and of steel castings; the investigation of the treatment during manufacture and hardening of spring steel; the examination of the qualities of special steel alloys, suitable for the construction of engine or machine details, in which exceptional strength and lightness are essential; and the production of alloys capable of resisting corrosion and withstanding great changes of temperature, and thus specially suitable for the construction of superheaters and other apparatus in which such changes occur.

We have in new steels a series of materials which promise to revolutionise a very important percentage of our machine work, and to necessitate very material alterations in the proportions of our machine tools, involving very heavy outlay, if we wish to advance with the times. Now these are facts pointing to the necessity for extensive research conducted in a thoroughly systematic way.

I have endeavoured to show how desirable it is that the engineer and the physicist should work together in dealing with certain investigations which I have enumerated, and I have done so because, although engineers generally now fully appreciate the aid which physical science can afford, there has not hitherto been such an intimate association of the two classes of workers as is really desirable. But with electrical engineering the case is quite different. We are accustomed to speak of the extraordinarily rapid development of electrical engineering, and the marvellous way in which it is assuming such a paramount position in civilised life,

but I do not remember ever hearing this wonderful growth attributed to what I believe to be its real cause, namely, that from the moment that the practical application of electricity became one of the branches of our profession, engineers and physicists have worked closely hand in hand to overcome its difficulties, and to elucidate the questions to which it gives rise. The growth of electrical engineering thus constitutes a great object-lesson, sufficient in itself abundantly to emphasise the fact that the future progress of engineering is indissolubly bound up with the progress of physical research.

THE SOUTH AFRICAN ASSOCIATION.

REVIEWING the brief history of the events which culminated in the first annual meeting of the South African Association for the Advancement of Science, the early proceedings of which were described in our issue for May 21, Sir David Gill, the president, announced some of the facilities which had been offered to induce the British Association to visit South Africa in 1905. The president read a letter he had received from Sir Gordon Sprigg, the Prime Minister of Cape Colony, stating that free railway passes will be granted over the Cape Railway system for all officials of the British Association, and a limited number of invited guests; and that a sum not exceeding 6000*l.* will be guaranteed towards the cost of passages to and from the Cape for the above-mentioned officials and visitors. This amount will be shared by the Governments of the Transvaal, Natal and the Cape. Sir David Gill went on to say that the other Governments had undertaken to share one-half of this responsibility, and to grant similar free use of their railways. There will be no lack of private hospitality, and the council of the British Association will recommend to the general committee of the Association at the Southport meeting next September that the invitation to hold the annual meeting in 1905 in South Africa be accepted.

Reference was also made to the value of a closer alliance between the results of scientific research and everyday practice in commercial pursuits, the classical works of several of the earlier investigators being mentioned as examples of the far-reaching effects of thorough and precise researches into common everyday phenomena. Sir David Gill then proceeded to enlarge upon the practical value of scientific research, and the reasons for its encouragement in the universities and colleges, and mentioned the unselfish work of Profs. Beattie and Morrison in undertaking the magnetic survey of South Africa, during 1897 and subsequent years, entirely at their own cost. He strongly urged that facilities should now be granted to them for completing this most important work, which fills a gap in the observations that are now being carried out in various parts of the world simultaneously with those being made by the various Antarctic expeditions in the South Polar regions.

Two papers read before Section A of the South African Association contained interesting statistics as to different aspects of the mining industries of the new colonies. In a paper on "Nitro-Glycerine Explosives: their Influence on Industrial Development," Mr. William Cullen, of the Modderfontein Dynamite Factory, stated that by means of explosives alone above 12,000,000 tons of ore had been milled in the Transvaal in the year prior to the war, but no estimate could be formed of the many million additional tons removed in developing shaft-sinking and so on. The old dynamite is rapidly becoming a thing of the past, and the more modern blasting gelatin has gradually supplanted everything else. Perhaps the most interesting part of the paper was that where the final triumph of nitro-glycerine in cordite and many similar powders was demonstrated, proving it to be not only the strongest disruptive agent, but also the mildest and easiest managed impellent.

Mr. W. A. Caldecott, in a paper on the "Cyanide Process from its Introduction into the Rand to the Present Day," said the immense importance of the process was shown by the fact that just before the war half the gold from the Rand was obtained by the cyanide process. By way of comparison, the writer stated that the Rand gold output in 1890 was 494,523 ounces milled, and only 286 ounces obtained by cyanide process. In three years the proportion grew to 1,147,960 ounces milled, and 330,510 ounces by cyanidation.

The records of meteorological observations made at the dynamite factory of Modderfontein, which extend over a large number of years, and form probably the most complete Transvaal meteorological record available, were discussed by Mr. William Cullen in Section A. Rainfall, barometric pressure, temperature (maximum, minimum and average), atmospheric moisture, wind velocity and wind direction were some of the meteorological data passed in review. All were illustrated by diagrams. The rainfall for the various years was analysed, and it was pointed out where a departure from the normal had great influence on the agricultural interests of the Transvaal, and on the prevalence of cattle diseases. The average rainfall for the past five years was 25 inches, the highest being 30·6, and the lowest 20·1, and the observations seemed to show that it was on the increase. The barometric readings showed a very slight variation all through the year, the maximum difference of about 14 generally coming in June, but every twenty-four hours the maximum and the minimum records always occurred at the same time.

Prof. S. Schönland, in a paper to Section B on stone implements in the Albany Museum, emphasised the persistence of the Palæolithic age in South Africa as compared with other countries: While, he said, the manufacturers of stone implements in South Africa were not devoid of skill which must excite our admiration, while their arrow-heads of perforated stone, their rolling-pins, their stone rings, indicated that there was not only skill, but an inheritance of trade tricks handed down from generation to generation, which were faithfully adhered to by the masters of the craft, it was astonishing that so far it had been impossible to find any evidence of progress in the manufacture of stone implements in South Africa, such as we knew had taken place in other countries from Palæolithic times to the time when stone implements were given up. Generally speaking, it could be seen that not only had the Stone age persisted in South Africa until comparatively recent times, but that the Palæolithic age had persisted there to the same extent. This was especially shown in the entire absence of polished stone implements.

Dr. J. D. F. Gilchrist dealt in the same section with the development of some South African fishes. It has been commonly alleged that the practice of netting, as carried on in the Zwartkops, the Buffalo, and other tidal rivers of South Africa, has proved destructive to the eggs and spawn of fish. On the commencement of trawling by the Government steamer in False Bay and on the Agulhas Bank, it was urged that the dragging of the net along the bottom of the sea caused the destruction of great quantities of the eggs and young of food fishes. The evidence obtained by an inquiry held by a Parliamentary Commission seems to indicate that many of the common fishes may deposit their eggs on the bottom of the sea. On the other hand, in all the instances where the mature eggs had been procured and successfully fertilised on the Government steamer *Pieter Faure*, they were found to float on the surface of the water, and only after the larvæ had been hatched out some time did they begin to sink to the bottom. It was also brought to the notice of the Commission that it had already been demonstrated in northern waters that there was only one fish of practical economic importance depositing its eggs on the bottom—the herring—and only a small species of herring of little value to the present fishermen occurs in the Cape seas. Recently facilities have been afforded by Government for more careful examination on shore of the eggs and larvæ procured by means of fine nets and from the mature fish. The eggs and larvæ were described of the white stumpnose, red stumpnose, silver fish, sand fish, zeverrim or zee-basje, kabeljaauw, horse fish, red gurnard, klip-fish (two species), sole (two species), and the blaasop, and the ova and larvæ of fish as yet unknown. The general effect of the investigations so far carried out was to confirm that the trawling did not interfere with the eggs of fishes that were of practical commercial value.

At a concluding general meeting of the Association on the last day of the proceedings, the council of the Association for the present year was elected in accordance with nominations received from the chief centres in Cape Colony, Rhodesia, Transvaal, Natal, and Orange River Colony.

At a subsequent meeting of the newly-formed council, Sir Charles Metcalfe was unanimously elected president for the ensuing year and the 1904 meeting to be held at Johannesburg.

The following officers were also elected:—vice-presidents, Mr. Sidney J. Jennings, Dr. Muir, Mr. Gardner F. Williams, and Mr. J. Fletcher (Natal); hon. secretaries, Dr. Gilchrist (Cape Town), and Mr. Theodore Reunert (Johannesburg); hon. treasurer, Mr. W. Westhofen (Cape Town).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. Darwin and Prof. Larmor have informed the Vice-Chancellor that certain donors desire to contribute a sum of 400*l.* a year, for five years, for the purpose of augmenting the stipends of two university lecturers in mathematics. The object is to enable the lecturers, whose present stipend is 50*l.* a year each, to devote themselves by study and research to the advancement of mathematical science. The donors hope that by additional contributions a sum may be procured which will enable the arrangement to be continued, should it prove successful in the first instance. The general board recommends that the offer should be gratefully accepted, and it proposes that it should be authorised to appoint in October two lecturers in mathematics, who, for the sake of distinction, and to commemorate two of the most eminent of Cambridge mathematicians, shall bear the title of the Stokes lecturer and the Cayley lecturer respectively. The new offices are to be tenable with university and college lectureships.

The general board has been in communication with the council of the Royal Geographical Society respecting the reorganisation of geographical studies within the University. It suggests that a board of geographical studies should be appointed, on which the Society should have representatives; that this board should arrange courses of instruction and administer funds; and that a special examination in geography for the ordinary B.A. degree should be instituted. The council of the Society has agreed to contribute 200*l.* a year for five years, to be met by a corresponding grant from the University, for the expenses of the scheme, and it is hoped that other contributions to the geographical fund may be received. The tenure of the present reader in geography expires at Midsummer, but the general board has postponed making fresh arrangements until the Michaelmas term, when a complete scheme is promised.

The annual reports of the Botanic Garden Syndicate and of the antiquarian committee have been published in the *University Reporter* for June 13. They record a large number of gifts to the collections from many sources.

The professorship of surgery and the new lectureships in electrical and mechanical engineering were duly established by the Senate on June 11. An election to the former will be made during the summer. The latter will be held by Mr. Lamb and Mr. Peace, the present demonstrators of applied mechanics.

At the same congregation the grace which brings to an end the long reign of Euclid, as the sole arbiter of geometry in the pass examinations, was passed without a dissentient voice.

Dissertations and memoirs, constituting records of original research, and qualifying for the B.A. degree, have been approved in the case of Mr. J. C. Simpson, Caius (pathology), and of Messrs. R. K. McClung and J. J. E. Durack, Trinity, Mr. F. Horton, St. John's, and Mr. M. Varley, Emmanuel (physics).

In the mathematical tripos, part i., Messrs. Bateman and Marrack, Trinity, divide the senior wranglership. For the third place four candidates are bracketed, Messrs. Gold and Phillips, St. John's, and Messrs. Barnes and Hills, Trinity. Miss P. H. Hudson, Newnham, is bracketed seventh wrangler. She is the daughter of Prof. Hudson, of King's College, London, and the sister of the senior wrangler of 1898. Her sister was bracketed eighth wrangler in 1900. Six men and one woman obtain first classes in part ii. of the tripos. In the mechanical sciences tripos, part i., thirty men obtain honours.

THE department of psychology and education of the University of Colorado publishes from time to time booklets dealing with the investigations carried out by its staff. The most recently published number is concerned with certain aspects of educational progress, and includes five original articles dealing with subjects as different as the function of habits and the English Education Act, 1902. Under the title "Miscellanea" are given extracts from educational papers published in different parts of the world, and amongst them are two from NATURE.

AN instructive example of the close connection maintained between the needs of the American commercial community and the technical colleges of the United States is provided by a recent announcement from Chicago. In response to requests from insurance companies, architects, and contractors, the Armour Institute of Technology of Chicago is now offering a four years' course in fire protection engineering, leading to the degree of bachelor of science. This course will be inaugurated in September next under the direction of Prof. Fitzhugh Taylor, formerly engineer of the Underwriters' Laboratories. The requirements for admission are to be identical with those for the mechanical, electrical, civil, and chemical engineering courses. A special feature of the course will be a series of lectures by prominent insurance officials, architects, and contractors upon the practical features of their work. The technical laboratory work of this course will be given at the Underwriters' Laboratories of Chicago. These laboratories, maintained by the stock fire insurance companies, are well fitted for the work, because all new devices, appliances, and materials that enter into the question of fire protection, or have a bearing on fire risk, are taken there to be tested.

THE papers relating to the appointment and resignation of Mr. M. E. Sadler, Director of Special Inquiries and Reports on Education, have been published in a Blue-book (Cd. 1602). It is evident from the documents that Mr. Sadler was anxious to secure that education should have an open-minded and impartial intelligence office as much as the War Office or the Admiralty. With this object in view, and the desire to obtain increased efficiency, Mr. Sadler asked for increased facilities for his work, including "the creation of a new post of scientific assistant in the office of the Director of Special Inquiries and Reports of the Board of Education. The increase in the number of cases, referred to the office of Special Inquiries and Reports, in the consideration of which an expert knowledge of scientific terminology and a general acquaintance with scientific investigation and discovery are indispensable, renders it desirable that one of the officers attached to the staff of the Director of Special Inquiries should be specially charged with the duties of scientific assistant." This was in 1900, but objection was raised to the proposal by the vice-president. An inquiry into the nature of the demands was then asked for by Mr. Sadler, but was not approved. The result of this and other suggestions showed that there was no desire to develop the work of the Special Inquiries Office, but rather to limit it. Matters came to a climax early in this year, when a request for permission to prepare certain reports was made, but was met with objections. Subsequently, the Director framed a memorandum setting forth further needs of the Office of Special Inquiries, and stating that without additional assistance he could not continue to hold himself responsible for the collection and supply of accurate and well-digested information on educational work at home and abroad. The Board of Education failed to agree with the proposals made, and laid down certain new conditions for the conduct of the Special Inquiries Office. The result was that on May 9 Mr. Sadler wrote:—"The arrangements which have been proposed to me for the future conduct of the Special Inquiries Office would, in my judgment, gravely impair the scientific thoroughness and independence of the work of the office, and prove incompatible with future efficiency," and on this account he resigned his post.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 28.—"On the Theory of Refraction in Gases." By George W. **Walker**, M.A., A.R.C.Sc., Fellow of Trinity College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

The present theories of refraction in gases lead to the formula $\mu^2-1=Nf(p)$, where N is the number of molecules per unit volume, and $f(p)$ is a function of the frequencies of the waves and independent of temperature. The measured variation of μ with temperature does not agree with this formula. There are several cases where μ^2-1 is much less than $K-1$, where K is the dielectric constant, and in such cases we find that, although μ^2-1 is approximately proportional to N, $K-1$ is nearly proportional to N/θ, where θ is the absolute temperature.

The present theories are thus inadequate to explain the actual facts.

The view adopted in the present paper is that instead of having free periods of vibrations, the molecules move in constrained motion. Regarding the atom as consisting of a positively charged particle united with a large number of small negatively charged particles, it is supposed that the negative particles roll on the surface of the positive one, but do not vibrate radially. The control on transmitted waves is thus the rotational energy of motion of the particles, and it must be proportional to the absolute temperature.

When, by collisions or otherwise, the rotational motion becomes so great that the electric attraction is overcome by the centrifugal force, ionisation occurs. The frequency or frequencies of rotation at which this occurs are determined by the electrical attractions, and are independent of temperature, although, of course, the higher the temperature the greater will be the amount of ionisation. These frequencies are regarded as corresponding to the spectral lines; this view explains the ionisation produced by ultra-violet light, and also agrees with the fact that luminosity is probably always connected with ionisation, *e.g.* the characteristic lines come out in the electrical discharge through the gas.

Regarded simply as obstacles, the molecules must contribute a term to μ^2-1, which is proportional to N and practically independent of the frequency. The final formula obtained is

$$\mu^2-1=k_1N+k_2N/\theta\ f(p,\theta),$$

where k_1 and k_2 are constants, and $f(p,\theta)$ is a function of p and θ. The function is fully discussed in the paper.

The formula is shown to be capable of accounting for all the known facts connected with the dielectric constant and the refractive index, while the absorption of ultra-violet light and apparent absorption, due to selective reflection in the infra-red, is also explained.

Notwithstanding the very complex and varied facts in air, hydrogen, carbon dioxide, ammonia and sulphur dioxide, complete numerical agreement between the measurements of $K-1$ and μ^2-1, as regards both absolute magnitude and dependence on pressure, temperature and frequency, has been established.

Chemical Society, June 4.—Dr. W. H. Perkin, sen., F.R.S., vice-president, in the chair.—The following papers were read:—Formation of an anhydride of camphoryloxime, by Dr. **Lowry**. This anhydride is formed when nitrocamphor is boiled with concentrated hydrochloric acid.—Mutarotation of glucose, as influenced by acids, bases and salts, by Dr. **Lowry**. The mutarotation of glucose is greatly accelerated by the presence of alkalis, less so by acids, and is not influenced by the presence of salts.—The solubility of dynamic isomerides, by Dr. **Lowry**. It is shown that in some cases the determination of solubility may be applied to the study of dynamic isomerides, thus the solubility of *pseudo*-β-bromonitrocamphor in benzene at 10° increases from 2·3 to 9·3 per cent., whilst a mixture of this with its isomeride dissolves to the extent of 14 per cent.—The rusting of iron, by Dr. **Moody**. It is stated that the rusting of iron is brought about by the initial production of ferrous carbonate by the action of atmospheric carbon dioxide on the metal, this salt being subsequently oxidised. The non-production of rust in presence of agents which destroy hydrogen peroxide is regarded as due, not as Dunstan suggested, to the destruction of hydrogen peroxide, but to the insolubility of carbon dioxide in solutions of these substances. In the discussion it was pointed out that the presence of impurities in the iron or in the reagents employed would materially affect the production of rust by inducing electrolytic changes, and that Dunstan had already pointed out that carbon dioxide exercised an accelerating influence in the production of iron rust.—Iminoethers corresponding with ortho-substituted benzenoid amides, by G. D. **Lander** and F. T. **Jewson**. The authors find that they get better yields of iminoethers by alkylation in an ethereal solution than in an alcoholic one, but even there nitriles are formed. They also find that whilst *o*-toluamide gives a yield of only 13·6 per cent., *p*-toluamide gives 70 per cent. of iminoether.—The hydrolysis of ethyl mandelate by lipase, by H. D. **Dakin**. It is shown that *i*-ethyl mandelate is unequally hydrolysed by this enzyme, the product being *d*-mandelic acid.—Isomeric change in benzene derivatives. The conditions influencing the interchange of halogen and hydroxyl in benzene diazonium hydroxides, by Dr. **Orton**.—The synthesis of $\alpha\alpha\gamma$-trimethylglutaric acid and its derivatives, by Dr. W. H. **Perkin**, jun., and Miss A. E. **Smith**.—Hexamethyleneoctocarboxylic acid and the *cis*- and *trans*-modifications of hexamethylenetetracarboxylic acid, by Messrs. **Gregory** and **Perkin**.—The bases contained in Scottish shale oil, part ii., by Messrs. **Garrett** and **Smythe**.—A direct method for determining latent heat of evaporation, by Dr. J. Campbell **Brown**. The weight of liquid evaporated by a determinate amount of heat, applied at the boiling temperature of the substance, is determined in a special apparatus.—The four isomeric hydrindamine-*d*-chlorocamphorsulphonates and isomeric compounds of the type $NR_1R_2H_3$, by Dr. **Kipping**. The isolation of the isomeric hydrindamine salts referred to in the previous paper affords conclusive evidence of the occurrence of isomerism among quinquevalent nitrogen compounds of this type. The author accounts for this isomerism by the assumption that the five valencies of the nitrogen atom are directed from the centre to the angles of a square pyramid.

PARIS.

Academy of Sciences, June 8.—M. Albert Gaudry in the chair.—On a new general relation between electromotive forces of saline solutions, by M. **Berthelot**. If an element formed by two saline solutions separated by a porous partition A and B has an electromotive force E, the element A+AB, formed by the two solutions A and AB, with electromotive force ϵ_1, and the element B and AB, with electromotive force ϵ_2, then the relation $E=\epsilon_1+\epsilon_2$ is found to hold good. The relation concerning the union of acids and bases, established by earlier experimenters, is a corollary to this more general case.—The formation of alcohol in the fermentation of plant juices containing sugar, by M. Armand **Gautier**. An attempt to distinguish analytically between a naturally fermented wine and a liquid artificially fortified with alcohol. Attention was paid especially to the various forms in which nitrogen compounds were present; estimations of glycerol and acidity were also made. It was found that the best characteristics of a really fermented liquid were the amount of volatile acid and the complete absence of ammoniacal nitrogen.—On the propagation of waves in a perfectly elastic medium affected by finite deformations, by M. P. **Duhem**.—Prof. Lorentz was nominated a correspondant for the section of physics in the place of M. Amagat.—On the results obtained by cannonading against hail storms, by M. E. **Vidal**.—On the integrals of the equation $s=f(x, y, z, p, q)$, by M. E. **Goursat**.—On differential equations of the third order which admit of a continuous group of transformations, by M. A. **Boulanger**.—The motion of a solid in a gaseous medium, by M. L. **Jacob**.—An examination of the conditions which determine the sign and the magnitude of electrical osmosis and of electrification by contact, by M. Jean **Perrin**. Electrical osmosis is intense only for ionising liquids; thus a marked effect was produced with water, methyl, ethyl, and propyl alcohols, acetone and nitrobenzene, but was absent with benzene, ether and turpentine.—On the external thermal conductivity of silver wires plunged in water, by M. E. **Ragovsky**. The wires were heated electrically, and a steady current of water passed at a measured rate through the tube surrounding the wire, observations being made

when a stationary state was attained.—Hypothesis on the nature of radio-active bodies, by M. Fillipo **Re.** An extension of the nebular theory to the formation of atoms. It follows from the hypothesis that radio-active bodies should possess a high atomic weight, and should give out energy owing to the contraction of their atoms.—Dissociation curves, by M. A. **Bouzat.** From an examination of thirty-five experimental results the following law is deduced:—in a group of univariant systems in which a solid body gives rise by dissociation to another solid body and a gas, the ratio of the temperatures corresponding to a given dissociation pressure in any two systems of the group is constant, whatever the pressure may be. The law has been verified for a range of temperature from 238° to 1065° (absolute), and of pressures from 300mm. to 1600mm.—On the action of arsenic on copper, by M. Albert **Granger.** When copper is heated with arsenic in an inert gas at 440° for a sufficient length of time, a definite crystallised copper arsenide is produced, having the composition Cu_5As_2. Phosphorus gives a corresponding compound.—On the qualitative and quantitative analysis of osmiridium alloys, by MM. **Leidié** and **Quennessen.** The alloy is attacked by fused caustic soda and sodium peroxide, the osmium and ruthenium separated in the form of the volatile peroxides, and the iridium as the double nitrite of iridium and sodium.—On the nutrition of plants deprived of their cotyledons, by M. G. **André.** The assimilation of organic material is lessened by the removal of the cotyledons, but the ratio of phosphoric acid to nitrogen is practically unaffected.—On the mechanism of the saccharification of the mannanes of *corrozo* by the seminase of lucerne, by MM. Ed. **Bourquelot** and H. **Hérissey.** The extract from *Phytelephas macrocarpa* contains a soluble ferment the hydrolysing action of which is complementary to that of seminase.—Research on indoxyl in certain pathological urines, by M. Julius **Gnezda.**—The mechanism of the emission of larvæ in the female of the European lobster, by MM. **Fabre-Domergue** and E. **Biétrix.**—On the iron ore of Troïtsk, by MM. L. **Duparc** and L. **Mrazec.**—Castration in man, and the modifications which result from it, by M. Eug. **Pittard.**—On the kinematography of barometric movements, by M. P. **Garrigou-Lagrange.** A series of charts of isobars, mapped out for equal intervals of time, has been studied by means of the kinematograph. The examination of the American charts has clearly shown that, in spite of their apparent complication in detail, there are in reality but two general movements of the atmosphere. These two movements have the effect of alternately opening and closing the two routes followed by American depressions. A study of European charts leads to similar conclusions, although the regularity is less marked than in America.—On the conflagration of balloons during landing, by M. **de Fonvielle.** The disaster of the *Pannewitz* was probably caused by the electrification of the balloon giving rise to a spark.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part ii. for 1903, contains the following memoirs communicated to the Society:—

February 21.—E. **Riecke**: Contributions to the theory of atmospheric electricity, iii., on the mass of the ions contained in the air.

F. **Krüger**: The theory of polarisation-capacity.

March 7.—W. **Nernst**: The determination of molecular weights at very high temperatures.

F. **Bernstein**: On the associated domains (Hilbert's *Klassenkörper*) of an algebraical domain (*Zahlkörper*).

E. **Riecke**: Contributions to the theory of atmospheric electricity, iv., on the "adsorption" of ions at the earth's surface.

DIARY OF SOCIETIES.

THURSDAY, JUNE 18.

ROYAL SOCIETY, at 4.30.—(1) Surface Flow in Crystalline Solids under Mechanical Disturbance: (2) The Effects of Heat and of Solvents on Thin Films of Metal: G. Beilby.—The Forces Acting on a Charged Electric Condenser Moving through Space: Prof. Trouton, F.R.S., and H. R. Noble.—On the Discharge of Electricity from Hot Platinum: Dr. H. A. Wilson.—The Bionomics of *Convoluta Roscoffensis*, with Special Reference to its Green Cells: Dr. F. W. Gamble and F. W. Keeble.—New Investigations into the Reduction Phenomena of Animals and Plants; Preliminary Communication: Prof. J. B. Farmer, F.R.S., and J. E. S. Moore.—The Action of Choline, Neurine, Muscarine and Betaine on Isolated Nerve, and on the Excised Heart: Dr. A. D. Waller, F.R.S., and Miss S. C. M. Sowton.—The Physiological Action of Betaine Extracted from Raw Beet Sugar: Dr. A. D. Waller, F.R.S., and Dr. R. H. Aders Plimmer.—On the Physiological Action of the Poison of the Hydrophidæ; Part II. Action on the Circulatory, Respiratory and Nervous Systems: Dr. L. Rogers.—The Spectra of Neon, Krypton and Xenon: E. C. C. Baly.—And other Papers.

LINNEAN SOCIETY, at 8.—Descriptions of New Chinese Plants: S. T. Dunn.—On the Life-history of a New Indian Species of Monophlebus: E. P. Stebbing.—On the Anatomy of Leaves of British Grasses: L. Lewton-Brain.—Scottish Freshwater Plankton.

FRIDAY, JUNE 19.

ROYAL INSTITUTION, at 9.—Radium: Prof. Pierre Curie (in French).

MONDAY, JUNE 22.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Explorations in Bolivia: Dr. Evans.

WEDNESDAY, JUNE 24.

GEOLOGICAL SOCIETY, at 8.—On a Transported Mass of Ampthill Clay in the Boulder-clay at Biggleswade: Henry Home.—The Rhætic and Lower Lias of Sedbury Cliff, near Chepstow: L. Richardson.—Notes on the Lowest Beds of the Lower Lias at Sedbury Cliff: A. Vaughan.

THURSDAY, JUNE 25.

UNIVERSITY COLLEGE MATHEMATICAL SOCIETY, at 5.30.—Some Present Aims and Prospects of Mathematical Research: E. T. Whittaker.

FRIDAY, JUNE 26.

PHYSICAL SOCIETY, at 5. (University of London, South Kensington).—(1) Electrical Effects of Light upon Green Leaves; (2) Blaze-Currents, (*a*) of a Vegetable Tissue, (*b*) of an Animal Tissue; (3) Quantitative Estimation of Chloroform Vapour in Air by (*a*) Oil Absorption, (*b*) Densimetry: Dr. Waller.—The Temperature Limits of Nerve-Action in Cold-blooded and in Warm-blooded Animals: Dr. Alcock.—(1) On the Movement of Unionised Bodies in Solution in an Electric Field; (2) On the Passage of Nervous Impulses through the Central Nervous System: Dr. Hardy.

THURSDAY, JUNE 25, 1903.

SCIENCE AND THE NAVY.

II.

IN a former article[1] we referred at some length to the new Navy scheme, pointing out that in our opinion the scientific education of naval officers, and therefore the whole naval service of the country, must be vastly improved by its provisions. Since this article appeared there have been debates in both Houses of Parliament, including a most important one on May 9, in which Lord Selborne in an admirable speech gave some new information concerning the proposed scheme of education, and on the 15th inst. a circular letter was issued relating to the selection, training, and advancement of navigating officers. There has also been much discussion in the public Press; in this, as was to have been expected, scientific questions have been only lightly touched; and when the engineer question has been broached, its relation to the Admiralty practice regarding the other officers who must possess high technical knowledge has not, in our opinion, been pointed out.

But when we pass from the criticism of the new arrangements to the first steps actually taken to give effect to them, the opinion is quite general that the Admiralty is to be entirely congratulated. Prof. Ewing, who may be looked upon as the creator of the admirable engineering school at Cambridge, thereby showing that his powers of administration and organisation are on a par with his scientific acquirements, has been selected to fill the post of Director-General of Naval Instruction; his duty, we take it, will, to a large extent, be to do for the *personnel* what the Director of Naval Construction does for the *matériel* of the fleet.

We may be convinced not only that with such a strong man as this at the helm the complete scientific instruction of officers will be insisted upon, but that practical laboratory instruction of the juniors in mathematics and pure science will be secured.

Indeed, we may go further, and say that they have already been secured in most admirable fashion, for Lord Selborne, in the speech to which we have already referred, spoke as follows :—

"Without pledging myself to exact detail, I will give a general sketch of the kind of education that will be given. It includes not only that special education for which the school will exist, but that general education which every officer and gentleman ought to have. History, geography, physical geography, English and French will be taught. I do not say that other modern languages will not be taught. Mathematics, algebra, arithmetic, trigonometry, mechanics, physics, laboratory work, seamanship, drill and engineering will be taught. There will be laboratories and workshops in which the boys will be accustomed to the use of tools from the very commencement. There will be vessels of all sorts for use and demonstration, from a launch to a battleship, and generally an effort will be made, while not neglecting the general education of the boys, to start them from the moment of their entering the college on the education of a naval officer."

[1] Vol. lxvii. p. 289.

When we compare this programme with the one hour a fortnight in physics in the *Britannia*, and no laboratory within sight, students of science well recognise that naval education for the future will be conducted on business principles, and we may again express our regret that such a system, *mutatis mutandis*, is still a thing to hope for in some dim distant future in the case of the Army.

In our former article we pointed out how the subject of navigation suffered generally from the absence of a school afloat for practical work similar to those provided long ago for gunnery and torpedo work. Not only is this defect in the system to disappear in the case of the junior officers, but as stated in the circular letter to which we have referred, the regulations for the instruction of navigating officers have been revised so that a definite course of practical training may be given them in a navigation school ship which is about to be established at Portsmouth, with a suitable staff of instructors. The course of instruction while they are attached to the school ship will last for ninety working days, part of the time being spent at sea in the ship and the remainder on shore. While going through the course they will live on the school ship.

After the candidates have qualified in the school they will serve for a short period in the large ships of the Mediterranean, Home and Channel fleets, so as to obtain experience under the navigating officers in the work of a fleet in regard to navigating duties.

It would be difficult to overestimate the importance of these new departures, about which very little has been said in the various discussions of the new scheme, although, in our opinion, they are precisely those by which the greatest benefit to the service will be secured in the future.

Leaving on one side the objections to the new scheme which have been based on prejudice or a complete ignorance of the changes in any naval service which the progress of science has rendered inevitable, we may say that the question of the possible interchangeability of the officers at some distant date has attracted most attention in relation to the new training of the Engineers. On this point opinion has rapidly grown in favour of the new scheme, since inquiry has shown what a large common basis of pure science underlies the proper performance of any one of the specialised duties. The objections, in short, have been held by advocates of technical education in its worst sense, that is, the rule-of-thumb carrying out of practical processes without any inkling of the scientific principles involved.

We indicated in our last article that, although the new scheme provides for a system of interchangeability when once it is in full working order, the present practice is vastly different, and as we consider this interchangeability of paramount importance from the point of view of utilising to the utmost the results of the complete scientific instruction of our naval officers to be provided in future, it is important to return to this subject in somewhat fuller detail to show the important bearing of another part of the new circular.

We may begin by saying that our present naval officers, so far as their *scientific* training goes, may

be divided into two categories, well trained and less trained; these are the equivalents of the "specialised" and "not specialised" of the Admiralty memorandum setting forth the scheme.

The well trained or specialised officers have to deal with (1) navigation (but so far without a navigating school), (2) gunnery with a gunnery school, and (3) torpedoes with a torpedo school. We may say that the lieutenants performing these specialised duties comprise roughly about one-third of the total numbers. They get special allowances for their special duties.

But it must at once be stated that there are many duties on board ship for the proper performance of which special training, not of a scientific character in the ordinary acceptation of the word, is equally required, and, of course, these duties have to be provided for. They are carried on by the "unspecialised" lieutenants, who are roughly twice as numerous as those who have received a full scientific training. These are employed as watch keepers and in connection with general ship duties. They are "deck officers" as opposed to the scientific officers. The less scientifically trained or deck officer gets little or no allowance; on the other hand he is expected to spend money in painting ship. We see then that under the present system the officers performing each particular piece of work, whether scientific or merely professional, are for the most part in water-tight compartments; there are differences in the amount of special instruction they receive, the kind of work they do, and the allowances they get.

It was pointed out in the previous article that according to the present practice the less scientifically trained officers get the lion's share of promotions; that, in fact, the promotion has been in the inverse ratio of the scientific nature of the work done.

It has been urged in defence of this practice that scientific knowledge is of less value in the higher ranks than that which is derived from a complete mastery of all the details of a ship's general organisation, which can only be gained by the constant performance of the "deck duties" to which reference has been made. So that if we take the navigator, the most important scientific officer, on the one hand, and the first lieutenant, the most important deck officer, on the other, the thing works out in this way. The navigator, because his duties are so onerous and are never changed, knows nothing of deck duties. The first lieutenant, because his duties are never changed, is unlikely ever to become a competent navigator. The navigator, because he has not had an opportunity of learning deck duties, has his promotion retarded so that he can never get on the active list of admirals. The first lieutenant, because he is necessarily familiar with deck duties, is the first to be promoted, and is thus sure of employment on the active list of admirals.

The baneful effects of such a system as this, which are two-fold, were fully set out in our previous article. The Admiralty indicated its contempt for scientific as opposed to mere professional training, and the Admirals' list was swamped by men who knew little of navigation, although this, of course, finds one of its highest outcomes in handling ships in tactical exercises and in order of battle.

It was next shown that while, as determined by the scheme, the interchangeability of all officers, including the engineer officers, *must* be secured ten years hence, there were reasons why the interchangeability of at least some of the duties of the existing executive officers should be commenced at once. We rejoice to learn from the new circular that this also is to be done.

Lieutenants (N.) will in future be placed on exactly the same footing as regards executive command and ship's duty generally as gunnery and torpedo lieutenants, and are not to be excused from any ship's duties except those which interfere with the special duties pertaining to them. They will be appointed and succeed to the position of first lieutenant, if a vacancy occurs, in all ships where a commander is borne exactly in the same manner as any other specialist officer.

In rendering the special report on the qualifications of a navigating officer, a further clause is to be added, dealing with his capabilities as an executive officer.

Further, midshipmen who show special aptitude are, whenever possible when the ship is under way, to be taken off other duties, and to navigate the ship independently from the after bridge, fixing positions on the chart, and bringing the result of such work to the navigating officer.

Instead of one commissioned officer taking sights and working the reckoning daily, arrangements are to be made, when practicable, for one junior lieutenant or sub-lieutenant to be taken partially off watch-keeping so as to work with the navigating officer for ten working days under way.

The officer thus told off is to be on deck when coasting, making the land, going in and out of harbour, &c., and is to be in every way encouraged to get an insight into navigating duties. If at the end of the ten days the captain is satisfied with his work, he will be relieved and another officer is to be told off for this duty.

These important changes can be urged on two grounds. In the first place, there is the obvious benefit to the Service which will be secured when all captains and admirals are made equally acquainted with both their scientific and professional duties by interchanging them while they are lieutenants and commanders. In the second place, the preparation and simplification of the carrying out of the new scheme, by which another class of specialised officers, the engineers, will be introduced in the future, will be vastly facilitated by organising and testing the best way of interchanging duties on a small scale over a limited area.

We have referred chiefly to the navigator among the scientific officers, and no doubt the Admiralty has dealt with him first, because his duties are the most specialised; but if the interchange is advantageous in his case, the other specialists will follow, and, speaking only from the scientific side, knowing nothing of professional difficulties to be surmounted, it seems to us that such a preliminary experimental study of the

problem which awaits the Admiralty in the future, and which, if faced along the whole line, at the same time, may prove of Herculean proportions and be fraught with dangers of breakdowns, must commend itself as a scientific method. Our view of the wisdom of such an interchangeability among the present officers is strengthened by information which has been furnished us as to the procedure in the German Navy, which enables us to compare the two systems, and in our opinion fully justifies the policy of the new circular.

The distribution of duties amongst executive officers of the German Navy is as follows. As in the British Service every officer is educated in seamanship, navigation, gunnery and torpedo service. In the course of their service the various qualifications of the officers are carefully noted, and especially if they show superiority in any one of the above-mentioned branches. Ships in the German Navy are commissioned for two years. The list of officers for any given ship is made out by the Admiralty at Berlin. The next senior officer after the captain becomes the executive officer. After him the officer who is most proficient (according to the returns) in navigation and pilotage is appointed as navigating officer, without regard to seniority as lieutenant. He who is most proficient in gunnery is appointed "artillery officer," and so with the torpedo officer. Qualification regulates the selection of each officer for special duties, not his seniority as lieutenant. The specialisation of an officer for any particular duty only lasts for the two years' commission. In the next commission the navigating officer may be artillery or torpedo officer, or an ordinary watch keeper without special duty. It is *exceedingly rare* for an officer to be appointed for navigating duties *for more than two years*, as the Admiralty require every officer to go through a probation as navigator *in order to ensure that captains who are responsible for the navigation of the ship shall know their work in that respect.* An apparently weak point in this system is that for a time after the appointment of an officer to navigating duties ships are not so well navigated as they might be, since for the first few months of his time the navigator is really learning his work. Gunnery and torpedo work may be learnt in harbour, but navigating can *only* be learnt by actual practice and experience at sea. But, on the other hand, the strength of this system is that all officers have practical training at sea as navigators *with a captain who has gone completely through the navigating mill,* and knows how to detect any failure in the navigator which might endanger the ship. For squadrons an officer who has shown good ability as navigator in a single ship is selected as navigator.

On this system, whilst ability in any branch (N., G. or T.) is recognised, an officer is not unduly specialised to the detriment of his knowledge in other branches of his profession. In the British Navy the gunnery and torpedo officers are occupied with their special duties nearly the whole of their time as lieutenant, but they go to deck duties when promoted commander, although their knowledge of navigation and the handling of the larger ships is practically nil. But the navigator is occupied in special duties when promoted commander as well as during his service as lieutenant, *some fifteen years in all at least,* and is allowed no practice in other branches of a naval officer's profession, and because he has not been allowed to have any such practice, he is discharged to the coast guard, his naval career is broken, and the Service loses a man who has had the best possible training for leading ships into action.

Surely this comparison shows that the question of interchangeability has already been considered in the German Navy on the lines which we indicated as beneficial for our own; and in this we see an additional argument why the preliminary trial which we suggested on scientific grounds in our own Navy, and to which the Admiralty now stands committed, should at all events be welcomed as a first step to the wider interchangeability to which the Admiralty is certain to be forced in the future, for of the progress and need of science in the armed service of a nation there will be no end.

THE DISTRIBUTION OF DISEASES.

The Geography of Disease. (Cambridge Geographical Series.) By Frank G. Clemow, M.D. Edin., D.P.H. Camb. Pp. xiv + 624. (Cambridge: University Press, 1903.) Price 15*s.* 6*d.*

THE present writer had occasion recently to endeavour to ascertain, from the literature available in London, the distribution of a particular tropical disease. After spending several months on the work, the conclusion left on his mind was that the task was impossible in London alone, and that similar work in continental libraries would have to be undertaken before an accurate idea could be obtained. There is another method possible in the study of distribution, viz. personal investigation in various countries into the occurrence of a particular disease. The difficulties in the way of this method are perhaps not so great as one would think.

A notable instance of what we mean has lately been afforded by Hutchinson in his study of the "fish" ætiology of leprosy. Not content with accepting all evidence second-hand, he proceeded to South Africa and India and inquired critically into the statements which had been made against his view, with the result that many if not all of the "facts" (such as p. 229, "leprosy is found to be *common* in people whose religion and customs forbid them to touch fish") quoted as opposed to his views he was easily able to show were not facts at all, but mere hearsay evidence, which by constant repetition is at last generally believed. Many instances of this kind have come within the writer's own experience. Thus when first the mosquito malaria theory was definitely established on a basis of fact, it was asserted in print over and over again that no mosquitoes existed in such a place, but that malaria was rife there. As it was important to examine into these statements, the circumstances were carefully investigated in each particular instance, with the result that the "facts" vanished into thin air.

Another striking example is Manson's theory of

Filaria perstans as the causative agent of sleeping sickness (p. 408). This view had prevailed in the text-books for some time, but the Royal Society's commission has shown at once that the facts will not support this view. These then are instances where a personal acquaintance of even a few months' duration of the disease under consideration has considerably modified received opinions. But we cannot always hope to have critical inquiries of this kind by trained observers. We are, unfortunately, left with the second much inferior method, viz. the diligent searching out of all that has been written on the diseases in question, more especially in the latest periodical literature. Here we are immediately confronted with the difficulty of knowing what to believe amidst the mass of published articles, and when we see some of the sources from which the author has only too frequently quoted, we consider that he has not had a due appreciation of the extremely untrustworthy nature of much of his material.

With this qualification then, viz. a too ready willingness to admit the statements of uncritical writers, we can only find praise for the large mass of material condensed by the author. To hope to find any general explanation of the distribution of diseases is, we think, at present premature. We may point out finally some details of particular diseases where the information is inadequate or inaccurately set forth. On p. 237, the principal carrier of malaria is said to be *A. Claviger*. This is a curious statement, seeing that it does not occur in tropical Africa, India, Malaysia, &c. Possibly the author had Europe alone in his mind. Nor should we think that Grassi holds that any species of Culex can transmit malaria. The malaria of cattle is quite a different disease from that of man, and it is not accurate to use this term in reference to pyroplasma bovis (p. 243). Again, the malarial statistics of India have been, up to the present, so notoriously untrustworthy that we doubt much the value of quoting statements about "an increased production of the poison" in famine years (p. 248). Nor is it true that the Central Provinces are among the most malarious territorial divisions of India.

Turning now to that peculiar manifestation of malaria, blackwater fever (p. 44), we note the omission of Palestine as an important focus of this disease. So virulent is it there among the Jews that some villages have been deserted. On p. 51 the author writes, "whether hæmoglobinuric fever in man is due to the same organism as the red water fever of cattle is uncertain." In our opinion it is absolutely certain that it is not, for the simple reason that this organism (pyroplasma) of cattle has a characteristic and easily recognised appearance, and exists in abundance in the blood and organs, but has never been seen or described by anybody in the blood or organs of blackwater patients. The recent commission on malaria appointed by the Royal Society has likewise shown that in the Duars (India) it is as common as in tropical Africa. Nor do we consider that an abundance of observations has been published tending to disprove Koch's views of blackwater; on the contrary, the Royal Society's commission was of precisely the same view as Koch.

Sprue (p. 127) undoubtedly exists in India, as a typical case from there in a lady came recently within our knowledge. It is quite certain, however, that the ætiology and differentiation of hill-diarrhœas in India is completely obscure at present. We have already referred to the work of the sleeping sickness commission, but it seems probable that when its complete reports are published our knowledge of the distribution of Filaria will be considerably modified.

While we have pointed out in what respect we consider this book deficient, yet it must not be thought that we have not a full appreciation for the industry which it must have necessitated; and those students who wish to possess a well-arranged book of reference on the distribution of diseases ought to be exceedingly grateful to the author, but when consulting it they should remember that the subject is hardly yet capable of accurate treatment. J. W. W. S.

HYDRODYNAMICAL FIELDS OF FORCE.

Vorlesungen über hydrodynamische Fernkrafte nach C. A. Bjerknes' Theorie. Von V. Bjerknes. Band ii. Pp. xvi+316. (Leipzig: Johann Ambrosius Barth, 1902.) Price 10 marks, or 11.50 marks bound.

THE first volume of this book, which was reviewed in NATURE for November 3, 1900, is of a theoretical character, and deals with the stream lines in a perfect liquid considered especially with reference to the motions set up by moving solids and in particular pulsating, oscillating, or moving spheres. In it were obtained results now well known to students of hydrodynamics showing the existence of attractions and repulsions between the spheres, bearing a considerable analogy to the forces occurring in gravitation and other physical phenomena.

The interest of these results is greatly enhanced by the experiments described in the present volume. These experiments were commenced in the summer of 1875 by the late Prof. C. A. Bjerknes, who observed that if two spheres lighter than water (croquet-balls were used in the first instance) are allowed to fall into a tank of water from the same height, so as to set up vertical oscillations at the surface, they will approach each other if let fall simultaneously, and will recede from each other if let fall so that their oscillations are opposite in phase. From the fact that the volumes displaced by the spheres vary, the conditions are in many ways analogous to those produced in an infinite liquid by "pulsating" rather than oscillating spheres. From this beginning more elaborate experiments were devised. A sphere falling in liquid in the neighbourhood of a vertical wall in which its image could be seen by reflection was found to reproduce the attractions and repulsions indicated by theory for a pair of spheres moving symmetrically. The next experiments were conducted with spheres so fixed as to perform pendulum oscillations below the surface. The experiments were first performed at home, but from 1876 to 1880 Prof. Schiötz arranged for their continuation in

the Physical Laboratory of Christiania, and during the last two years Mr. S. Svendsen assisted in the work. About 1880, Prof. C. A. Bjerknes received from the Norwegian Government a private laboratory, where the experiments were arranged by the author with the assistance of Mr. J. L. Andersen. The result of these facilities was the construction of an elaborate instrument for measuring the attractions and repulsions of bodies pulsating in liquid. The generator consists of a system of pumps or drums operated on as bellows by cranks worked by a handle. These alternately force air in and out of the "pulsators," which may consist either of elastic balls, drums, or similar arrangements suspended in the water by a "pulsation balance," and the whole apparatus is now supplied by Ferdinand Ernecke, of Berlin. Another form of apparatus is described suitable for studying bodies oscillating in water without change of volume. Methods are also described of rendering the stream lines visible, and diagrams are shown illustrating the resemblance of these lines to magnetic lines of force.

The description of the experiments occupies the second part of the book. The first part consists of a summary of the main results, both quantitative and qualitative, which were established in vol. i., treated by elementary methods only, and it serves the purpose of enabling the physicist to read the present volume without studying its more mathematical predecessor. For such a reader the third part will have considerable interest, for it deals with the analogy of hydrodynamical phenomena with those of electrostatics and magnetism. Prof. C. A. Bjerknes's original discussions of these analogies having been given at a transition period in the development of electrical science, the writer of the present volume has largely remodelled the arguments in order that they may be studied in the light of modern electrical views. Between hydrodynamical and electric or magnetic fields of force, a close analogy exists *except in regard to the sign of the force*. The stream lines due to spheres executing pulsations of the same phase are identical with the lines of force due to like charges, but the pulsating spheres attract one another while the electrified spheres repel one another. If the pulsations are of opposite phases, the stream lines are the same as the lines of force of oppositely charged bodies, but the force is repulsive instead of attractive. Owing to this difference, the hydrodynamical field is to be regarded as affording a representation rather than an explanation of electric and magnetic fields, and as Prof. V. Bjerknes points out, a negative representation is still a representation, and it may admit of all the uses of a positive one.

Prof. V. Bjerknes has uniformly adopted the Heaviside system of "rational" electrical units, and he points out the great simplifications that arise from the use of this system, expressing his regret that the existing units were adopted before the advantages of the rational system had been fully appreciated.

The book will be read with much interest by physicists, and the reproduction of some of the experiments in the lecture room suggests a useful aid to the teaching of electricity. G. H. BRYAN.

FARM ACCOUNTS.

The Farmer's Business Handbook. By I. P. Roberts. Rural Science Series. Pp. xiii+300. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 4s. 6d. net.

THIS volume of the Rural Science Series consists firstly of an elementary account of book-keeping suitable to a small farm, and secondly a discussion of such legal questions as leases, tenant right, highways, fences, mortgages, taxes, &c., with which an ordinary farmer is likely to become conversant in the course of his business. This latter portion of the book is naturally only applicable to the United States, and though succinctly and clearly written, can be of little service to the English reader. In the earlier section of the book a system of book-keeping is set out by which the farmer can ascertain not only his profit or loss as a whole, but the result of his operations on each field or in each section of his business. The usual method of double entry is employed, though only day book (for which the American equivalent is apparently "blotter") and ledger are kept. The explanations are clear and simple, and may be read with profit by students who are beginning formal book-keeping, and are getting confused over the problem of Dr. and Cr. But we are by no means convinced that the ordinary system of double entry is the best method of handling farm accounts; naturally it can be made to deal with them, and for the cash account nothing different is wanted, but it is an extremely cumbrous means of ascertaining the profit or loss on individual crops or classes of live stock. Farmers are often reproached, and justly enough, with not keeping proper accounts, but it is not quite so easy a matter as in a business where all the items are in sight. So many of the figures must be estimates depending upon the judgment of the farmer; first of all the annual stock-taking has to be a valuation, in which market fluctuations have, or have not, to be considered, according to the purpose of the account. For example, a man has a breeding flock the number of which remains constant; in ascertaining his profits upon sheep-breeding it is best to take the value of the flock as constant, but in ascertaining his financial position at a given moment, he must re-value the flock at current rates. Again, many operations upon a farm are performed as much for their contingent advantages as for immediate return; the dung and cultivations given to the root crop have their value throughout the rest of the rotation; cattle are fattened for the sake of the manure they produce.

To one point the author of this book very properly gives special prominence, the item of household expenses; the house rent, the milk, potatoes, &c., consumed, the labour spent, are very often not taken into account at all, and the farmer sometimes comes to the conclusion that his farm is not paying when he is really living beyond his income. On the whole we believe that the ideal system is to open a ledger account for all cash transactions and for the house, and to keep separate running or progress accounts against the main branches of his business, such as the dairy

herd, sheep, crops, the latter account being occasionally specialised for a few years in order to ascertain whether a particular crop or field is paying its way. But we commend to the teachers of book-keeping in such of our agricultural colleges as possess a farm the problem of devising with an open mind an improved system of farm accounts, which shall be simple, actual, and helpful.

OUR BOOK SHELF.

The Rôle of Diffusion and Osmotic Pressure in Plants. By B. E. Livingston. Pp. xiii+149. (The University of Chicago Press, 1903.)

BIOLOGISTS who attach importance to the bearing of physics on their science must be gratified with the increasing number of books now appearing on such subjects as are treated in the book before us.

Mr. Livingston's short book is clear and readable, and contains a simple and concise sketch of much of the physics of diffusion and solution. The matter is well put, and difficulties are avoided. But concise treatment has its disadvantages, and, in one or two places, a false conception might be obtained from the author's descriptions. Thus there are notable exceptions to the rule that the particles of substances are brought closer together during the change from the liquid to the solid state. And it is scarcely fair to assume that the greater closeness of the particles is the cause of the greater rigidity of solids.

The limited space available in the book has apparently led to the exclusion of matter which it would be essential for the biologist to be acquainted with, and he should supplement it with the study of some text-book of physical chemistry. With regard to recent work, it must be regarded as unfortunate that the writer leaves out all mention of Brown and Escombe's work on diffusion through perforated septa from the physical part of the book, while in part ii., on physiological considerations, this investigation receives a bare mention by name in a small footnote. One would have thought that these authors' results would have been fully discussed as having a most intimate connection with the subject, and as bringing a completely new light to bear on our ideas of the diffusion of gases and of dissolved substances in plants.

The chapter on the terminology applied to solutions of different concentrations is very lucid, and should prove most useful to biologists.

In part ii. an account of turgidity and of absorption and transmission of dissolved substances in plants is given. Much information is imparted in a small space considering how nebulous are our ideas on the actual part played by the vital osmotic membranes of plants.

In the reviewer's opinion, far too much weight is accorded to Westermeier's and Godlewski's hypothesis explaining the ascent of water in trees. These writers assumed that the elevating force is to be found in the exudation pressure of the cells of the wood, cortex, and medullary rays. The physical relations of these cells to the water capillaries of the plant render the idea that the cells at different levels act as relay pumps impossible.

The theory of a tensile transpiration current is alluded to, but unfortunately it is criticised in the light of Copeland's undoubtedly misleading experiment.

The later chapters of the book are devoted to the osmotic effects of the medium on plants, and summarise most interestingly the recent results of osmotic and chemical fertilisation. H. H. D.

Mechanical Refrigeration. By Hal Williams, A.M.I.Mech.E., A.M.I.E.E. Pp. xiii+406. (London: Whittaker and Co., 1903.) Price 10s. 6d.

THIS book, which is devoted mainly to practical study of mechanical refrigeration and cold storage, should have a wide circulation, dealing as it does with a growing industry of which the literature, so far as text-books are concerned, is remarkably scanty. It opens with two chapters on the theory of heat engines and refrigerating machines. The first of these might well have been omitted, as it merely contains a series of definitions which can only be intended for a trader who is totally ignorant of the elementary theory of heat, and are somewhat apt to convey a wrong impression. The second chapter, on thermodynamics, is carefully worked out, the section dealing with the heat change consequent on the performance of internal work by the fluid being particularly interesting. A chapter devoted to the history of the subject leads to a short study of the methods of preparing the modern refrigerants, liquid carbonic acid and ammonia, and a description of the more important type of refrigerating machinery. In the latter section the author has confined himself to an account of ammonia and carbonic acid plant, and in this, considering the dimensions of the work, he is undoubtedly justified. Fifty pages of the book deal with the auxiliary plant necessary in a cold storage works. Finally, insulation, ice making, the construction and arrangement of cold storage works, and the application of methods of refrigeration to commercial processes are fully dealt with. The author wisely omits all mention of liquid air and its problematical applications. The book is well illustrated by means of photographs and diagrams, and the text is clear and concise. M. W. T.

Die stammgeschichtliche Entstehung des Bienenstaates sowie Beiträge zur Lebensweise der solitären u. sozialen Bienen (Hummeln, Meliponinen, &c.). Herausgegeben von Dr. H. von Buttel-Reepen. Pp. xii+138. (Leipzig, 1903.) Price 2.40 marks.

THIS is a book that should not be overlooked by those who are interested in the many important questions that are opened up by the habits of social insects. The author points out that the highly developed organisation of the life of the hive-bee does not stand alone, but may be traced up from the commencement of mere association of solitary species, through the less organised communities of humble-bees, &c., to its perfection in the hive-bee. A great number of outlying questions respecting parasitic bees, wax-secretion, &c., are also more or less fully discussed. The author is very anxious to eliminate, so far as possible, the natural tendency to anthropomorphise the actions of bees to too large an extent, and appears to take the view that inherited tendencies have to a large extent rendered their actions subjective and automatic. The index is very full, and is preceded by a list of nearly 200 books and papers dealing with the subject, which cannot fail to be of great value to any serious student of bee-life.

The Mind of Man. By Gustav Spiller. Pp. xiv+552. (London: Swan Sonnenschein and Co., Ltd., 1902.)

MR. SPILLER suffers apparently from the constitutional defects of extreme prolixity, and a marked contempt for the views of psychologists who have the misfortune to prove themselves "unscientific" by disagreeing with himself. The reader who is ready to overlook these deficiencies will find much interesting discussion of the principal problems of psychology in his book, though scarcely, I think, any considerable fresh contributions to the science. The author's fundamental point of view may be indicated by his definition of

psychology as the study of the functional needs of the central nervous system. His book exhibits great psychological learning, but is marred, I believe, by an ineradicable inconsistency of principle. He does not seem to have definitely made up his mind whether the processes of mental life are truly teleological (as he verbally asserts) or purely mechanical (as he frequently implies). Thus he exalts the significance of habit, or, as he calls it, "organised reaction," and minimises that of pleasure, pain and volition in determining action to a degree which leaves it a mystery how a new purposive reaction ever gets established.

A. E. T.

Heredity and Social Progress. By Simon N. Patten, University of Pennsylvania. Pp. i+214. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 5*s.* net.

Useful as analogy may be for purposes of illustration, it forms a precarious basis for scientific argument. Dr. Patten's book exemplifies the danger of attempting to formulate general laws on the strength of more or less superficial resemblances between phenomena belonging to diverse natural conditions. Such first-sight correspondences may legitimately be employed in the way of suggesting or indicating an underlying law, but in the absence of verification by comparison with all related facts, they are incapable of carrying an induction beyond its preliminary stages. These principles, which would seem to be sufficiently obvious, are practically ignored in the present work, which accordingly, in spite of some clever reasoning, is vitiated throughout by its faulty method. The author's premises being unsound from the outset, his arguments cease to be of interest except as exercises of logical ingenuity. A few examples will show the kind of biological doctrine to which Dr. Patten asks our assent. It is not such as to justify confidence in either his facts or his method. "The germ cell. . . has, therefore, the conditions of consciousness and more readily may be assumed to be the seat of consciousness than any other part of the body. In fact, by a process of exclusion it would seem to be the only possible seat of consciousness." "The nerve, in its effort to emit its sex products, presses against the skin and partially breaks through. The skin hardens over the injured part and the tooth results, which holds the nerve in." "The brain . . . is a sex organ that never attains its elementary functions." "The play of the emotions is sufficient to account for the reduction and disappearance of organs." It will be seen that the author is not to be taken seriously. His book is simply a monument of misapplied ingenuity.

The Educational Systems of Great Britain and Ireland. By Graham Balfour, M.A. Second edition. Pp. xxxi + 307. (Oxford: Clarendon Press, 1903.) Price 7*s.* 6*d.* net.

THE first edition of Mr. Balfour's book was published five years ago, and since that time events of the greatest importance have taken place in English and Irish education. The consequence is that the present issue differs in many respects from the previous one. To students of education the volume is already well known, at least by name, and in its enlarged form it should prove of great assistance to members of the new education authorities being formed in all parts of the country as a consequence of the passing of the Education Act, 1902.

The education of the British Isles is considered under the three headings—elementary, secondary, and higher, but, as Mr. Balfour says, this is likely to be increasingly difficult, as the three grades are becoming parts of that organic educational whole which it is essential to form in this country. There is one direction in which the value of the book might be much enhanced, and that is in showing what has been done in this country by private effort for higher education. No educationist has yet instituted an exhaustive comparison between the extent of private munificence in aid of higher education in this country and in the United States, though a beginning was made in NATURE (No. 1750). Such a comparison would do much to quicken public interest in higher education. The book may be recommended to all who wish to obtain an accurate and comprehensive idea of the present state of education in the British Isles.

A. T. S.

Alpine Flora. By D. J. Hoffman, translated by E. S. Barton. Pp. xii+112. (London: Longmans, Green and Co., 1903.) Price 7*s.* 6*d.* net.

IT is a notable fact that many travellers who have little or no knowledge of their native flowers often become keenly interested in the flora of the Alpine regions, and the reason is not far to seek, for the attraction lies in the richness of colour and lavish abundance which characterise the flowers growing on the mountains. There is therefore a demand for a book, with illustrations, preferably coloured, and written in fairly simple language, which will enable the amateur or novice to name his botanical specimens. Such is mainly the object of the present book, originally written in German and translated for the benefit of English travellers. It is naturally a difficult matter to decide which flowers to represent in a small book of moderate price, the limitations of which are imposed by the cost of production of coloured plates, and the selection is on the whole judicious. There are a few plants, such as *Hacquetia epipactis, Lilium carniolicum,* which are not found, or rarely so, in Switzerland and the Tyrol, which might have been excluded in favour of others of more common occurrence. The colour contrasts are good, excepting for a weakness in the tone of the pinks, and a similarity of blue in the gentians. Mrs. Gepp has introduced more precise terms in the English edition, which add to its scientific value, and yet should not offer any difficulty to the amateur, since a glossary is provided. The book may advantageously be used with Gremli's "Flora für die Schweiz," and will be a material help to those botanists who have not previously visited the European Alpine ranges.

Arnold's Country-Side Readers. Book i., pp. 144; price 10*d.* Book ii., pp. 176; price 1*s.* Book iii., pp. 214; price 1*s.* 2*d.* Book iv., pp. 236; price 1*s.* 4*d.* (London: Edward Arnold, n.d.)

Arnold's Seaside Reader. Pp. 264. (Same Publisher.) Price 1*s.* 6*d.*

THE title of the first four of these reading books for schools suggests that the reading lesson should be utilised to give the pupil some knowledge of the natural objects of the country at the same time that he is learning to read, and there is much to be said for such a plan. An examination of the contents of the volumes shows that much interesting information about common plants and animals is placed before the young learner; but there is so bewildering a medley of fairy tale with descriptive natural history that the boys and girls who are set to learn from the books will scarcely be able to decide where fancies end and facts begin. The same diversity of contents characterises the "Seaside Reader"; instructive lessons on fishes and other sea animals are interspersed with accounts of naval battles and biographical sketches of naval heroes. On the whole it would be wiser in such books to exclude the fairy tales and historical chapters; there is romance enough about natural science without other aid being necessary. The books are well printed and attractively illustrated.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Fœtal or New-born Giraffes Wanted.

WILL you give me the opportunity of making a request through your columns to museum curators and African sportsmen? I am especially anxious to obtain for study, preserved in spirit or dry, the head (*not* the prepared skull) of a new-born giraffe or of a late fœtal individual in which the boney ossicusps of the horns are already formed. I should be able to return the specimen after examination to the owner if desired. I should be glad to examine several such heads were it possible to procure them. All expenses of transport would be paid by me. I venture to ask those who can help me to communicate with me without delay.

E. RAY LANKESTER.

Natural History Museum, Cromwell Road, London, June 23.

Seismometry and Gëite.

BEFORE making a few comments on Prof. Milne's second letter under the above title (NATURE, June 12, p. 127), I should like to express my warm appreciation of his devotion to seismological research, and the great impetus it has given to observational work. In pure seismology—apart from applications of elastic solids to earth problems—Prof. Milne's reading is doubtless more extensive than mine, but if he is correct in regarding my first letter as containing nothing new to seismologists, they must, as a class, be singularly prone to a policy of *meliora scio deteriora sequor*. Novelty in results is, of course, much a matter of opinion. When Prof. Milne says, however, that there is no occasion for my warning as to Young's modulus, I must in reply give a quotation from his first letter, relating to the material of his hypothetical core, "it follows that the density . . . is 5·96, or approximately 6. *The* elastic modulus for a core of this density which conveys vibrations with a speed of at least 9·5km. per second is 451×10^{10} C.G.S., or roughly speaking, a little more than twice the Young's modulus for Bessemer steel." The italics are mine. If "the modulus" is not Young's modulus, E, a comparison between it and the E for steel is misleading, because a comparison of numerical results naturally implies that they refer to the same physical quantity. On this view the statement is doubly misleading, because there are *two* wave moduli, viz. $m+n$ and n. If, as one would infer from Prof. Milne's second letter, "the" modulus was intended for the wave modulus $m+n$, the futility of the comparison becomes obvious when we remember that on the ordinary theory $(m+n)/E$ may have any value between 1 and ∞, according to the value of Poisson's ratio. As a matter of fact, "the" modulus must, I think, have been intended at the time for Young's, though this must have escaped Prof. Milne's memory. If it were meant for $m+n$, we should have $(451 \div 5{\cdot}96)^{\frac{1}{2}}$ "at least" 9·5, whereas it is really only 8·7. If, however, we multiply 451×10^{10} by 6/5—which would be correct if 451×10^{10} were a Young's modulus in a material where Poisson's ratio had the uniconstant value 0·25—and substitute this, we deduce a wave velocity of 9·53km. per second.

Prof. Milne seems to have misunderstood my treatment of the two wave velocities in the *Phil. Mag.* (March, 1897, p. 199), and as it bears directly on the question at issue, I should like to make it clear. In previous papers I had advanced a variety of considerations pointing to the conclusion that, whilst all applications of elastic equations to the earth are more or less speculative, the mathematical and physical difficulties are enormously reduced when we suppose that the deep-seated material—about which we have no direct information—is nearly incompressible, *i.e.* has a Poisson's ratio approaching 0·5. Such a hypothesis, for one thing, rendered it unnecessary to assign to the rigidity and Young's modulus values largely in excess of anything yet encountered at the earth's surface. There remained, however, the fact of the high velocities observed in the more rapid earthquake waves, which had been generally supposed to imply enormously large Young's moduli, such, for instance, as the value 45×10^{11} given by Prof. Milne. The problem stood as follows:—

In an infinite isotropic elastic medium there are necessarily *two* wave velocities. If we know them both we can deduce all the elastic properties of the medium, provided we know the density; if we do not know the density, we can still deduce Poisson's ratio. If the medium is not infinite, but is bounded by a plane surface, then, as shown by Lord Rayleigh, there is a special type of surface wave the velocity of which, especially when the material is nearly incompressible, approaches closely to that of the slower or rigidity body wave natural to the material. If the bounding surface be not plane, but spherical or spheroidal, there is doubtless a wave answering to the Rayleigh wave, which within moderate distances of its origin may be expected very closely to resemble the Rayleigh wave in type, when the depth to which it penetrates and the wave-length are both very small compared to the central radius. If the medium have a Poisson's ratio of 0·25, the velocities of the two body waves must be in the ratio of $\sqrt{3}$(or 1·73) : 1.

In the earth there seems distinct evidence of only two types of waves. For the more rapid, supposing them to travel straight through, Prof. Milne himself would apparently take 10km. as the most probable value at depths below the immediate heterogeneous crust. It was important for my object not to understate this velocity, and I took the somewhat higher figure of 12·5km. The second type—which Prof. Milne terms the "large" waves—travel much slower. If they go straight through, their velocity is *less*, of course, than if they travel along the surface. On the former hypothesis, Prof. Milne might make them a trifle slower than the value I took, viz. 2·5km. per second. If, instead of 12·5 and 2·5, we took 10 and 2, we should obtain, of course, the same value of Poisson's ratio as before, 0·48 approximately, with a value for E somewhat *less* even than the very moderate value (about 10×10^{11} C.G.S.) obtained in my paper. If we took 10 and 2·5, or even 10 and 3, for the two velocities, we should get 0·47 and 0·45 for the values of Poisson's ratio.

The uncertainty as to whether the "large" waves were body waves or surface waves—or, as I thought more likely, a combination of the two—was not overlooked, as Prof. Milne's letter might suggest, but was dwelt on at some length in the paper. If they are *entirely* surface waves, the heterogeneous nature of the earth's crust, and the irregularities of mountain and ocean, are such as to introduce extreme uncertainty into any mathematical calculations. In this event it is doubtful whether any conclusion can be drawn either for or against the hypothesis of great incompressibility in the core; its explanation of the high velocity in the faster waves would, however, be unaffected.

The discussion of magnetograph results by Prof. Milne in the B.A. Reports for 1898 and 1899 (1888 is surely a misprint) was familiar to me as a contributor of data, but it did not seem to render my letter unnecessary. I suspect, however, that I partly misunderstood Prof. Milne's letter on this part of the subject, as I did not fully realise that he did not recognise the distinction between anomalous and merely high values of the horizontal force H. The fact that H is nearly twice as large at Batavia or Bombay as at Kew is natural, owing to their proximity to the magnetic equator. Whether the values at these stations are higher or lower than one would expect from their geographical position cannot be said with certainty until the completion of magnetic surveys. What my letter suggested was the advantage for critical purposes of records at a station where there is known to be a true *large* magnetic anomaly—*e.g.* in N.E. Ireland or the Scottish Highlands. Variations in the value of g are, relatively considered, trifling compared to those in H, and the larger gravitational anomalies present systematic features to which there seems no parallel in magnetics (*c.f.* Bourgeois' discussion of g in the "Rapports présentés au Congrès International de Physique," Tome iii., Paris, 1900). Apart from the question of the unit, I am a little puzzled by Prof. Milne's gravitational data for Kew, and I should warn him that there, as at some other stations, the agreement between different observers at different times has not been such as to warrant much reliance in any one observer's value for $g - \gamma$ (*i.e.* gravity observed less calculated).

C. CHREE.

Phenomena of Vision.

YOUR correspondent, Mr. W. Betz, refers in his letter of May 7 to the fact that an object just screened from direct vision by the nose (or by any other obstruction) becomes visible if we rotate the eye in a direction away from the object. This is a well-known phenomenon, and a very interesting one on account of the curious facts with regard to vision that can be deduced from it; but it is not in any way due to spherical aberration. It is rather a perspective effect, being caused simply by the shifting of the point of sight, which, being situated near the crystalline lens, moves laterally as the eye is rotated about its centre. There are several ways of demonstrating the movement of the point of sight, but the experiment described by Mr. Betz is perhaps the most convincing.

An interesting corollary of this experiment is the generally unfamiliar fact that we employ two points of sight simultaneously in the act of vision, though we may use one eye alone. Speaking generally, the eye wanders over any object we may be examining with slight pauses at each point of interest. Only at each pause do we really see, and our final mental impression of the whole object may be described as a mentally combined image of a series of "snap-shots." The retinal image produced at each "snapshot" is a perspective view with the node of the crystalline lens as the station point. The final mental picture is, however, a view with the centre of the eyeball (or its centre of rotation) as a station point. This latter view is smaller than the other, by reason of the fact that the centre of rotation is some little way behind the crystalline lens, hence the apparent size of an object varies as we study it. The general effect is further complicated by the lateral movement of the crystalline lens, which causes each momentary snapshot to be taken from a different station point; also the final impression is more or less influenced by the impression gained during the last fixed glance. Therefore we may conclude, with a considerable amount of reason, that we do not see objects exactly as they are. Really we only see a combination of a number of views taken from different points, and to arrive at a true understanding of what we see we must employ our capacity of reasoning. The extraordinary complexity of our mental visual conception is often deceptive, though unconsciously so to many people who have no idea of the peculiarities of vision.

The various effects of the employment of the two station points are not likely to be appreciated unless looked for, but once you realise the fact, evidence is easily collected. One of the most striking effects is the apparent movement of fixed points. In the experiment described by Mr. Betz the object point seems to play hide and seek with you, popping out from behind the screen when you look in another direction, and dodging back again when you try to look straight at it. It seems to move with the eye, but this effect is due mainly to the presence of the screen, for under other conditions it will generally be found that the apparent movement is opposite to that of the eye. The following experiment illustrates both the illusion of movement and also the dependence of apparent size upon the direction of vision.

Place two objects at different distances from the eye and subtending a moderate angle at the eye so that both can be seen when one is directly looked at. Look fixedly at one object and estimate the distance between the two. Then traverse the eye slowly on to the other object, and the distance between them most distinctly alters, the effect being apparently due to a shifting of one or both of the objects. You will find it somewhat puzzling to account for all the various effects of movement that can be detected under different conditions, but if you take all factors into consideration, you will, I think, eventually find that the shifting of the station point is primarily responsible for all the effects produced, other than those due to spherical aberration.

C. WELBORNE PIPER.

May 15.

MR. PIPER'S explanation of the curious phenomenon pointed out by Mr. Betz is presumably correct; that there are two station points used in vision can, however, scarcely be demonstrated. The positions of the nodal points of the eye are shifted during accommodation for near vision, and perhaps this displacement is what Mr. Piper refers to. In general it is difficult to observe the apparent motions of objects which Mr. Piper mentions, and it is still more difficult to trace such motions to the optical properties of the eye, since we are here dealing, not with optical images which can be directly examined, but with mental impressions. Thus König pointed out (*Wied. Ann.*, xxviii. pp. 367–368, 1886; "Gesammelte Abhandlungen zur physiologischen Optik," xiii. p. 58, Leipzig) that patients, on first being provided with strong divergent spectacles, complain that, on moving their eyes without turning their heads, stationary objects appear to move. After a time this apparent motion ceases to be observed, or, indeed, to be observable, but on removing the spectacles stationary objects appear to move in a sense opposite to that previously observed with the spectacles. In this case a readjustment of judgment respecting visual impressions has been effected; the result shows to what a great extent judgment enters into the act of vision.

EDWIN EDSER.

June 13.

School Geometry Reform.

IN the unsigned review of Prof. Barrell's "Elementary Geometry" appearing in the issue of June 18, the following sentence occurs:—"A feature to be noticed is that the author gives three meanings of a plane angle, in the last of which the angle is regarded as the plane space swept out by a line of indefinite length (one way) turning about one end." It is unsafe to say that such a definition is wrong, but it is certainly most undesirable in a school book. The apprehension of the true nature of an angle is one of the greatest difficulties that the beginner has to encounter, and the way is not smoothed by the introduction of the idea of an infinitely extended space. It is true, as Mr. Russell points out ("Principles of Mathematics," p. 416), that the definition can be made logically satisfactory if the axiom of the whole, being greater than its part, be rejected; but this is an intolerable objection. The best course for an educational book is that adopted by Ronché and De Comberousse ("Traité de Geometrie," 1891, p. 5), who say:—"La considération de deux droites qui se rencontrent conduit à une idée nouvelle, qui est celle d'*inclinaison* mutuelle ou d'*angle*, et qui, comme l'idée de longueur, ne saurait être définie, c'est-à-dire ramenée à une idée plus simple."

R. W. H. T. HUDSON.

June 22.

RECENT EXCAVATIONS AT NIPPUR.

IT was in 1884, at a meeting of the American Oriental Society, that the first plans of an expedition to Southern Babylonia were projected, and from that year dates the beginning of the systematic scientific work which is being carried on by the Americans at the mounds of Nuffar, the ancient Nippur, with all possible thoroughness. Since the year 1888, there have been four expeditions sent out to excavate this ancient site, and there is still much to be done there. The first resulted in the discovery of a Parthian palace, and many "finds" from systematic diggings in the Temple of Bel, the cuneiform tablets alone numbering two thousand; but ill-luck overtook the members of the party, and, owing to trouble with the Arabs, the camp was burnt and they themselves were robbed. However, the next year, on reopening the works, there was no opposition, and the labours of the expedition were rewarded with eight thousand tablets of the second and third millennium B.C., and in the third campaign many pre-Sargonic ruins were discovered, besides more than twenty thousand tablets. The last expedition, which came to an end in 1900, was the most successful of all; the Parthian palace was completely explored, and, what was more important, the great library of the Temple of Bel was located, and twenty-three thousand clay tablets were excavated therefrom, thus bringing the total number found up to more than fifty thousand.

Looking at the results of the four expeditions, we are struck with the careful way in which all operations have been conducted, especially towards the end of the period. The mounds were carefully surveyed, and even a relief map of them was made in plaster, the buildings which were discovered were accurately mapped, numerous photographs were taken of the various phases of the diggings, and as time went on those in command became even more methodical in their diggings. The manner in which the excavations were carried on merits the highest praise.

The "section" of the shafts dug through the mounds, as figured by Prof. Hilprecht in his latest work, "Explorations in Bible Lands" (p. 549), shows, as is common in ancient mounds, that the city was occupied from a very early period, and that from time to time new builders superimposed their pavements and dwellings upon those of an earlier period, so that the mounds are made up of successive layers, each marking an earlier building as the shafts sink lower. The diggers first cut through soil containing Sassanian and early Arabic remains. Then came the great Parthian fortress of the second or third century B.C. Next were found in six successive strata the pavements of buildings of (*a*) Ashurbanipal, who restored the great *ziggurat*, or temple-tower (*c.* 668-626 B.C.); (*b*) Kadashman-turgu (*c.* 1350 B.C.); (*c*) Ur-ninib (*c.* 2500 B.C.); (*d*) Ur-gur (*c.* 2700 B.C.); (*e*) Lugal-surzu (*c.* 3500 B.C.); (*f*) Sargon and Naram-Sin (*c.* 3750 B.C.). Below these, and beneath the level of the surrounding plain, a vaulted drain came to light, of a period distinctly before Sargon, and in the heart of the mound, on a slightly higher level, was a pre-Sargonic *ziggurat*. Straight down through these layers, from almost the top to the very water-level, a Parthian well had been sunk, a total distance of about seventy feet in depth. The mound of Nippur is therefore similar to Hissarlik and Tel-el-Hesy in the superimposition of cities.

The larger of the two Parthian buildings was a palace and fortress occupying what had been the centre part of the old Babylonian temple, and was an almost rectangular building surrounded by an enormous double wall, five hundred and sixty feet long on its south-eastern front. From the discovery of great masses of water-jars piled together in the southern part, as well as various fire-places and other kitchen arrangements close to them, it is clear that these were the servants' quarters, storehouses and bakeries. In the centre of the whole building rose the citadel, built over the ancient *ziggurat*, and it was through this that the only well of the whole building had been dug, evidently with the idea of the garrison holding out against a long protracted siege.

The smaller Parthian palace, west of the Chebar, which has been completely excavated, was a square building, measuring each side about 170 feet. It apparently had but one entrance, which was situated in the centre of the north-west façade. The walls varied in thickness from three to eight and a half feet, and the material used in the construction was brick, baked and unbaked. The roof, as the pieces of charred wood discovered in the ruins plainly show, was of palm logs, matting and earth. Prof. Hilprecht divides the building into two almost equal parts, the one for public functions and the other for the family life.

But important as these two buildings were, their interest cannot compare with the discoveries of earlier Babylonian ruins. Of these the huge *ziggurat*, or tower of the Temple of Bel, stands out pre-eminent, a huge brick building, the origin of which dates back to pre-Sargonic times, and shows in its various strata traces of the handiwork of the many kings who restored and added to it. According to Prof. Hilprecht, the Temple of Bel (called Ekur in the cuneiform inscriptions) was divided into two principal buildings, the *ziggurat* or great tower, and the "House of Bel." The whole was surrounded by the great wall called *Imgur-Marduk*. It is to this temple that the energies of the excavators have been principally directed, and from it have come the majority of the tablets found. The temple in Babylonia was not only a place wherein the gods might be worshipped, but was also a college at which priests were trained, and for this a reference library was essential. Consequently, it is not going too far to say that probably every important temple in Assyria and Babylonia had its own library of clay tablets. An excellent idea of what the temple rooms looked like may be gained from the photograph in Prof. Hilprecht's book, "Explorations in Bible Lands," p. 509.

In the remains of this Babylonian city many discoveries were made which add considerably to our knowledge of the daily life of the inhabitants. One of the most remarkable things found was a baking furnace made of brick, dating back to the third millennium B.C., composed of a series of seven (originally nine) parallel arches over a fire-box, which ran lengthwise through the whole kiln. It was, in fact, very similar to the military field-ovens in use at the present day. Still earlier is the specimen of the elliptical arch which Haynes discovered, which Prof. Hilprecht assigns to the fifth millennium B.C. This is undoubtedly the first Babylonian arch known, and will go far to prove the much-disputed question of the origin of the arch.

Up to the present comparatively few of the tablets discovered in the ruins have been published, so that it is impossible to speak of the possibilities of the great temple library. We may notice, however, an important clay map of Nippur, photographed in Prof. Hilprecht's book (p. 518), which gives the environments of that ancient city as they were about two thousand five hundred years ago. Interesting, also, are the "practice" tablets, written by the pupils in the schools during their study of the Babylonian language. Indeed, it is to this class of tablet that we owe much of our knowledge of the classical works in cuneiform, for many similar are preserved in the British Museum which are inscribed with excerpts from the Creation legends, syllabaries, and incantations.

Much remains to be done at Nippur, and it is to be hoped that the Americans will continue and complete the great work they have begun. There is little doubt that when the mounds of Assyria and Babylonia have yielded up their hoards of cuneiform tablets stored up in the palace and temple libraries, our knowledge of those countries will equal, if not surpass, what we know of the archæology of Greece and Rome.

MATHEMATICAL REFORM AT CAMBRIDGE.

THE syndicate appointed in December, 1902, to consider what changes, if any, should be made in the regulations affecting the mathematical portions of the pass examinations of the University of Cambridge has recently presented a report which has just been adopted by the Senate, and will profoundly and beneficially affect the teaching of the subject in our public schools and throughout the country.

Recognising the widespread desire for reform, noting the changes that have already been made in the schedules of important examining bodies, and having examined the recommendations of various committees, the syndicate is convinced that changes are desirable, and that a "modification of the requirements of

examinations is a necessary preliminary to any substantial improvement in teaching."

The syndicate has, therefore, made recommendations affecting the subject-matter of the Previous Examination. The alterations will begin to operate in the Lent term of 1904, and will finally supersede the present regulations after October, 1905. The principal changes may be summarised as follows:—

(1) In demonstrative geometry, Euclid's Elements shall be optional as a text-book, and the sequence of Euclid shall not be enforced. The examiners will accept any proof of a proposition which they are satisfied forms part of a systematic treatment of the subject.

(2) Practical geometry is to be introduced, along with deductive geometry, and questions will be set requiring careful draughtsmanship and the use of efficient drawing instruments.

(3) In arithmetic, the use of algebraical symbols and processes will be permitted.

(4) In algebra, graphs and squared paper work will be introduced; and a knowledge will be required of fractional indices and the use of four figure tables of logarithms.

The scope of the subject-matter in geometry is set out in two schedules. The first gives a list of constructions in practical geometry. We venture to take exception to one detail in this list, that of requiring a construction for drawing a common tangent to two circles. Why insist on first finding the points of contact? This may have been necessary under Euclid's postulates, but it should now be discarded; it is not practical geometry.

The second schedule indicates the amount of book work necessary in preparing for the Previous Examination. The propositions enumerated are nearly all contained in the Elements, but a judicious amount of pruning has been effected in the latter. Hypothetical constructions are permitted. The theory of incommensurables is not required.

The increase of freedom now being given to teachers should lead to further developments in the reform as experience is gained. It will be one great advantage to have the several branches of the subject brought into closer association and reacting on one another.

Geometry will be made generally interesting and will at last have a chance of being taught in a manner suited to boys. In looking out for suitable numerical examples in geometry, we predict that a good teacher will not fail to make use of functions of angles. Probably three figure tables of chords, sines, cosines and tangents will be sufficient, reading to tenths of a degree, and occupying a very modest space. A boy's interest will be stimulated when he discovers the latent power residing in these innocent looking tables. And in checking his graphical results, he may be led on to the numerical solution of right-angled triangles before he has heard of trigonometry, and will never afterwards be repelled by the symbols sin., cos., tan.

The employment of logarithms is most important. Their use illustrates the significance of fractional indices. And here again the interest of a boy must surely be aroused when he finds himself in possession of a new, unforeseen, and most valuable means of calculation.

The introduction of graphs is of great value. The fundamental idea of the representation of position and change of position by means of rectangular coordinates is thus acquired early and in an agreeable manner. Some teachers find that it is quite possible to go on without much delay to easy illustrations of the calculus.

Looking ahead to possible developments, the graphical use of polar coordinates to mark position and change of position, by the plotting of lengths and angles, might serve as an introduction to the study of vectors, a subject of first importance, and at present so woefully neglected.

We regard this reform at Cambridge as an important step in the movement now in progress throughout the country, and we hope to see it carried much farther before crystallisation takes place.

THE UNIVERSITY OF LONDON.

THE presentation for degrees of the University of London, which is to take place in the Albert Hall as we go to press, under the presidency of the Chancellor, Lord Rosebery, is noteworthy in several respects. For the first time in the history of the university, honorary degrees are to be conferred, the recipients being their Royal Highnesses the Prince and Princess of Wales, Lord Kelvin, and Lord Lister. The Prince is to receive the honorary degree of Doctor of Laws, the Princess that of Doctor of Music, and Lord Kelvin and Lord Lister that of Doctor of Science. Ordinary degrees are also to be conferred on 414 persons who have obtained them during the past year. Moreover, the occasion is remarkable as being the first gathering of representatives of all the different institutions and groups of persons connected with the university.

The reconstituted university has opened up new avenues of work in connection with schools, with university extension, with the colleges, medical schools, and polytechnics; students are entering both for the ordinary matriculation examination and for post-graduate study and research in unexpected numbers. The educational forces of London have, in fact, been organised by the university, and public interest is being shown in the work. But, as Sir Arthur Rücker, the principal, has pointed out, while there are many grounds for hope, and while the university is doing its best to make itself worthy of public support, it can never fulfil its duties without the supply of funds from public or private sources on a very large scale. We trust that one result of the brilliant ceremony on Wednesday evening will be an increase of the endowment of the university sufficient to secure the full development of the scheme which has already produced such satisfactory results.

NOTES.

FOR the first time for about forty years the Royal Society of Edinburgh, on the evening of June 6, held a conversazione. Lord and Lady Kelvin and Sir William Turner received the guests. There were many interesting exhibits from several departments of the Universities of Edinburgh, Glasgow, and St. Andrews, from the Geological Survey of Scotland, the Scottish Antarctic Expedition, &c. Prof. McIntosh, of St. Andrews, sent over a large collection of pearl shells and animals, living and dead, and great interest was taken in Prof. Ewart's exhibition of hybrid ponies. Some of the lantern exhibits were particularly attractive, notably the projection on the screen of tanks of living worms, crustacea, &c., and a fine selection of slides made from Piazzi Smyth's "cloud" negatives. Among the inventions and novelties exhibited, Dr. Halm's instruments for mechanically correcting stellar observations and for solving Kepler's problem in any given case, and Dr. Hugh Marshall's petrol incandescence lamp are worthy of mention.

CAPTAIN AMMUNDSEN'S Magnetic North Pole Expedition left Christiania on June 16 on board the ship *Gjoa*.

WE regret to announce the death, on June 10, of Prof. Luigi Cremona, director of the engineering school of the University of Rome.

THE summer meeting of the Institution of Naval Architects was opened at Belfast on Tuesday, and Lord Glasgow delivered his presidential address.

THE retirement of Sir James Hector, K.C.M.G., from the directorship of the Geological Survey of New Zealand and of the Colonial Observatory is announced by the *Victorian Naturalist*.

MR. MARCONI'S manager at Glace Bay, Nova Scotia, states that the company is transmitting daily wireless messages from Table Head to Poldhu, but the replies are being cabled pending the installation of machinery at Cornwall.

THE *Times* announces that Commander Don Julian Irizar, Naval Attaché to the Argentine Legation in London, has been appointed to command the vessel *Uruguay*, which will be sent by the Argentine Government in October to the Antarctic regions in search of Dr. Otto Nordenskjöld's South Polar expedition, which was joined at Buenos Ayres in 1901 by an officer of the Argentine Navy.

A GRANT of 5000 dollars, and travelling expenses to the amount of 1500 dollars, has been made to Prof. Arthur Gamgee by the Carnegie Institution for the preparation of a report on the physiology of nutrition, the object being to enable him to secure information which may lead to the organisation in the laboratories of various countries of cooperative research in the important problem of human nutrition, &c.

PROF. STEINMANN, of Freiburg, and two of his fellow-geologists of the same University, have arranged an expedition to the Central Andes of Bolivia. The party will start in August for Buenos Ayres, whence the route to be taken is *viâ* Jujuy, Tarija, Sucre, to Cochabamba. After a prolonged stay in the mountains the explorers will probably work their way to Antofagasta *viâ* La Paz. The outfit is of the most modern description, and Dr. Hoek, who is a member of the expedition, is one of the most capable German mountaineers.

THE International Fire Prevention Congress convened by the British Fire Prevention Committee will be opened at Earl's Court on Monday, July 6, by the Lord Mayor of London, who will be accompanied by the Burgomaster of Brussels. The general and sectional discussions will be held on the forenoons of July 7, 8, and 9. The testing operations and inspections are fixed for the afternoons of these days.

THE Royal Statistical Society announces the next competition for the Howard medal (1903–1904). The essays must be sent in on or before June 30, 1904. In addition to the medal, a grant of 20*l.* will be awarded to the writer who may be the successful competitor. The subject is "The Effect, as Shown by Statistics, of British Statutory Regulations, Directed to the Improvement of the Hygienic Conditions of Industrial Occupations." Full particulars may be obtained at the office of the Society, 9 Adelphi Terrace, Strand.

THE concluding meeting of the thirty-eighth session of the Aëronautical Society of Great Britain will be held on the Sussex Downs this afternoon. On this occasion will take place the international kite competition (wind and weather permitting) for the silver medal of the Society, in accordance with the rules and regulations drawn up by the council of the Society and the jury of the competition. Amongst those who have consented to act on the jury are Dr. W. N. Shaw, F.R.S., Prof. C. V. Boys, F.R.S., Mr. E. P. Frost, Sir Hiram Maxim, Dr. H. R. Mill, Mr. E. A. Reeves, and Mr. Eric Stuart Bruce.

WE learn from the *Lancet* that Dr. Loudon, of St. Petersburg, has published some interesting observations relative to the action of the Becquerel rays on the nervous system and on the eye. He found that when a box containing bromide of radium was placed in a cage in which mice were kept the animals became paralysed and comatose, and died in five days. He also found that persons who are either totally blind, or have only the feeblest possible perception of light, are peculiarly sensitive to the Becquerel rays, and are able to form visual conceptions of the contour of objects the shadows of which are shown on a screen by means of the rays.

THE following note referring to observations of sunrise at Stonehenge on Sunday appeared in Monday's *Times*:—For the first time for nearly ten years visitors to Stonehenge yesterday morning saw the sun rise over the altar-stone. There was an almost cloudless sky, and at forty-three minutes past three the sun appeared above the horizon and rose in a direct line over the altar-stone. It was a magnificent sight, and after a moment's silence the crowd gave a mighty cheer. There were some hundreds of people present, many of them having travelled in previous years many miles during the night preceding the longest day in the hope of seeing the sight which was seen under such favourable conditions yesterday morning.

SLIGHT earthquake shocks were felt in North Wales and Anglesey on the morning of June 19. Mr. Fred. C. Carey, of the County School, Bethesda, writes to us that the first shock was felt by him in the county school at 10.8 a.m. precisely, when a distant rumbling noise, lasting about a minute, was heard, and the whole building shook. Slighter tremors followed at 10.12·5, 10.16, 10.19·5, 10.27, and 11.11·5. At Carnarvon the buildings trembled violently. At Bangor the shocks were felt at about the same time. The bells rang at the railway station. The post office at Llanrug was much shaken. The shocks were general throughout Carnarvonshire, and were felt as far as the southern part of the Isle of Man. The vibration appeared to travel in a north-westerly direction. In Anglesey the shock was comparatively slight.

IN connection with the meeting of the International Meteorological Committee at Southport during the British Association week in September next, it is proposed to make arrangements for an exhibition of meteorological appliances and other objects of meteorological interest. Upon the initiative of the Meteorological Council, with the co-operation of the Royal Meteorological Society and the Scottish Meteorological Society, a committee has been formed to carry out this proposal. It is proposed to group the exhibits into four classes:—(*A*) meteorological statistics; (*B*) weather telegraphy; (*C*) atmospheric physics, including (*a*) meteorological photography; (*b*) instruments and instrumental records; (*c*) high level stations, balloons and kites, observations and records; (*d*) experimental illustrations; (*D*) the relation of meteorology to other branches of physics.

THE weekly weather report issued by the Meteorological Office for the week ended June 20 shows that over the southern part of England the rainfall was three times as much as the mean, while in the east of England it was more than seven times as great. Further, that the rain-

fall since the beginning of the year is in excess of the average in all districts, varying from more than 10 inches in the north of Scotland to 0·9 inch in the north-east of England. During the first three weeks of this month the amount measured near London was upwards of 6 inches; the Greenwich records for the last 60 years show that the heaviest previous fall in June was 5·80 inches, in the year 1860. At Malin Head the fall in the same three weeks was only 0·05 inch, and at Holyhead only 0·4 inch. But on June 22 an area of low barometric pressure reached our western coasts and occasioned heavy rain, amounting to an inch and three quarters at Valencia in the forty-eight hours ending 8h. a.m. on June 24.

The cleanliness of electric lighting has always been urged as one of the great claims in its favour, and it has been justly pointed out that the saving effected in redecoration partly balances its extra cost. Although this is true, electric light cannot be regarded as perfectly clean; it has long been noticed that there is a marked tendency for dust to accumulate on electric light fittings and wires, and on the walls and ceilings in their immediate neighbourhood. This is partly, no doubt, due to the air currents produced by the local heating, but it is also partly an electrical phenomenon. The dust particles floating in the air are presumably at air potential, and are consequently attracted to the conductors on the non-earthed side of an earthed system; they either stick to these permanently, or remain on them until charged, when they are projected on to and stick to the walls. The defect has naturally become more marked with the increased use of 200-volt systems. If switches are always put, as they should be, in the non-earthed wire, the deposition of dust will only occur during the time the lamps are alight, and will be minimised. Mr. D. S. Munro, writing in the *Electrical Review*, points out that a still further improvement can be effected by using concentric flexible conductors instead of the ordinary twisted cord, the outer conductor being connected to the earthed side of the system.

Dr. Edington read a paper at the recent meeting of the South African Science Association upon the occurrence of an epidemic among domesticated animals in Mauritius, in which trypanosomata were found in the blood. It attacked cattle, mules, horses, and donkeys, among which it caused an alarming mortality, and seemed to be allied either to nagana or to surra.

The commemoration day proceedings of the Livingstone College were held at Leyton on June 10. The College trains missionaries in the elements of medicine and surgery. The Bishop of St. Albans, who presided, stated that there could be little doubt that the average life of a man abroad was considerably extended when due care was taken to observe the rules of health. He referred to the importance of training women as medical missionaries for work in India, and to the moral effect exerted upon native races by curing their bodily ailments.

The annual return showing the number of experiments performed on living animals in the United Kingdom during 1902 has been issued as a Parliamentary paper (186). In England and Scotland the number of licensees was 319, of whom 112 performed no experiments. The total number of experiments performed by these was 14,906, of which 2130 were carried out under anæsthetics, and the remainder, 12,776, were of the nature of hypodermic inoculations. The inspector, in his report, directs attention to the large number of experiments performed for the preparation of remedies and on behalf of various public authorities. Five licensees alone performed 3857 inoculation experiments for testing anti-toxins, and fifteen licensees 3997 inoculations for public bodies for the purpose of testing milk for tuberculosis, for the examination of sewage and of air, and the like. As regards Ireland, 13 licences were in existence during the year, and 65 experiments were performed under them.

We have received from the director of the Survey Department, Cairo, a report on the meteorological observations made at the Abbassia Observatory during the year 1900, together with mean values for Alexandria for the previous ten years: also monthly results for Port Said, Assiut and Omdurman for part of the year 1900. The report is a very valuable contribution to Egyptian climatology, and bears evidence of every care having been taken in the selection of trustworthy instruments and in the reduction of the observations. The observatory is now well supplied with automatically registering instruments of the best patterns, including Dines's anemometer, Callendar's electric recorders for dry- and wet-bulb platinum wire thermometers, Campbell-Stokes's sunshine recorder, and Milne's seismometer. For Abbassia hourly observations are given, and the results, with daily and annual variations and other data, are shown in clearly drawn diagrams, both for this station and for Alexandria. From the latter ten-year series we note that the mean of the highest temperatures recorded in each month was 36°·6 C. in May, and of the lowest maxima 21°·6 in January; the mean of the highest minima was 22°·7 in August, and of the lowest 7°·0 in January. The extreme values were 40° and 5°·4. The mean annual rainfall is only 9·53 inches; most of this falls between November and January. No measurable quantity falls in June, July and August, and only three-tenths of an inch, on the average, in September.

In our recent notice of Messrs. Burroughs Wellcome and Co.'s "tabloid" preparations for photographers, we remarked that, among a very large assortment of reagents and mixtures, mercuric chloride and ferrous oxalate appeared to have been overlooked. The firm informs us that the mercuric iodide and sodium sulphite intensifier is so efficient that it does not consider the issue of mercuric chloride tabloids as desirable. We would point out that intensification is the only process subjected to such a limitation, and that, although the iodide of mercury method is easily applied and the tabloids are excellent for the purpose, there is no method of intensification that is so simple in its chemical and physical effects, and so trustworthy as to the amount of change produced and the permanency of the resulting negative, as the use of mercuric chloride followed by ferrous oxalate. The same advantages that we have indicated in connection with photographic "tabloids" apply also to the same firm's "'soloid' microscopic stains." A dozen or more varieties are already issued, the most recent addition being Leishman's modification of Romanowsky's stain for blood films. Microscopists will appreciate not only the convenience of being able to prepare staining solutions without having to weigh the solid substances, but also the fact that these preparations are made from materials specially selected for the purpose.

In *Science* for May 29, Mr. C. A. Chant discusses certain questions connected with theories of colour vision, and in particular a view put forward by Dr. Kirschmann according to which colour sensation may not be due to the effect of rays of one particular wave-length, but rather to the superposition of rays of different lengths the *combination* of which produces the effect of colour. That the theory in question is a possible one arises from the fact that "nobody

has seen light of one wave-length," and even in the narrowest band obtainable by a pure spectrum, differences of frequency amounting to many millions of wave-lengths may occur. Mr. Chant, on the other hand, refers to the experiments of Rowland, Michelson and Morley, Perot and Fabry in obtaining interference effects with very long differences of path (other experiments in this direction were recently noted in NATURE), and to the fact that not only was there no sign of the colour disappearing when the light approached perfect homogeneity, but the intensity of the sensation was slightly increased.

THE article on the infection-power of ascospores in the Erysipheæ is continued in the *Journal of Botany* (June) by Mr. E. S. Salmon. The ascospores of *Erysiphe graminis* growing on barley were found to be capable of infecting two allied species, but failed when sown on four other species of Hordeum, as well as on wheat, oats and rye. This establishes the existence of biologic forms in the ascospore stage similar to those known for the conidial stage. In the case of the form under investigation, the same species of Hordeum are proof against infection whether by ascospores or conidia.

THE announcement was recently made of the discovery of a new source of indiarubber, the peculiarity being that the latex, which has been found to yield a good marketable caoutchouc, is obtained from the underground portion of the tree, a Landolphia. The genus is confined to Africa, more especially to the tropical regions, and is characterised by the presence of latex in the stem, but the latex only furnishes caoutchouc in a few species. Of these the three best known, *Landolphia Kirkii, L. owariensis*, and *L. florida*, are llianes climbing by means of tendrils. Recently the new species *Landolphia Thalloni* has been exploited in the French Congo; the aërial portions of this species persist only for one or two seasons, and the latex is stored in the rhizome.

THE whole of vol. lxxiv. part ii. of the *Zeitschrift für wissenschaftliche Zoologie* is occupied by the first instalment of a dissertation, by Prof. A. Schuberg, on the nature of intercellular tissue. Among other results, it is demonstrated that the tissue between the cells of the epidermis is readily distinguishable from the corresponding structure in the true skin.

IN the April number of the *American Naturalist*, Prof. W. Patten describes certain fragmentary remains which, in his opinion, justify the conclusion that the primitive fish-like creature Trremataspis (previously known only by the dorsal shield) was furnished with a pair of oar-like swimming appendages attached to the head, and resembling those of Pterichthys and Bothriolepis. If this be so, it is probable that similar appendages likewise existed in Pteraspis, Cyathaspis, and Polyaspis.

IN an article entitled "The Ways of Nature," published in the June number of the *Century Magazine*, Mr. J. Burroughs discourses in a popular style on the question whether the lower animals really possess self-consciousness. Probably, he argues, they think without knowing that they think, and thus the faculty in question is restricted to man. Later on reference is made to incidents quoted in well-known works which seem to show that animals are really possessed of reasoning powers, but it is pointed out that since these incidents were, in most cases, at any rate, not recorded by trained scientific observers, their value must be largely discounted.

IN the report of the Marlborough College Natural History Society for 1902, the secretary states that, notwithstanding the season having been unfavourable for field-work, there are no reasons to be dissatisfied with the results of the year. The collections which have been most largely increased are those of the various groups of insects, especially Diptera. The members, it is stated, have been urged to specialise their studies, as it is considered that by this method the best results are ensured for future years. Whether this is really so there may, however, be two opinions.

ACCORDING to the annual report of the Cambridge Museums and Lecture Rooms Syndicate for the past year, considerable progress has been made in transferring the collections of the Woodwardian Museum to the Sedgwick Memorial Museum in Downing Street, where the geological lectures have been delivered. Amongst the more important additions to the University collections, special attention is directed to a valuable series of human skulls obtained from various sources, also to the skeleton of a humpback whale, presented by Mr. Rothschild, and to specimens of the whale-headed stork (*Balaeniceps rex*), the gift of Sir Reginald Wingate. During the twelvemonth the Zoological Museum has likewise been enriched by the gift, from Prof. Newton, of several collections of birds and eggs of exceptional value.

M. É. RECLUS has reprinted his interesting little book "Les Primitifs," which was originally published in 1885. The book is well known to English readers under the title "Primitive Folk: Studies in Comparative Ethnology" (The Contemporary Science Series); it deals with the Eskimo, Apaches, and various tribes of southern India. Nothing new has been added to the original edition.

DR. FRANZ BOAS has published as *Bulletin* 27 of the publications of the Bureau of American Ethnology the Tsimshian texts he collected at the mouth of the Nass River in 1894 while he was engaged in researches under the auspices of the British Association Committee on the North-western Tribes of Canada. By far the greater number of these are myths of the tribes in which the miraculous is blended with the actual; it is not difficult to eliminate the former. The remainder gives a good insight into the everyday life of the people. The texts are printed as they were taken down by Dr. Boas from his informants, and a literal word for word translation is given, as well as a more free rendering. In addition to their linguistic value these texts afford the reader a good idea of the literary style and the sentence-building of the Tsimshian Indians without a previous knowledge of the language being necessary.

A REPORT on the Kangaroo Hills Mineral Field, by Mr. W. E. Cameron, has been issued by the Queensland Geological Survey. The district is one of altered sedimentary rocks and granite, in which tin, copper, and silver mining has been carried out. A report on Yorkey's Gold Field and the Marodian Gold and Copper Field in the district of Wide Bay, Queensland, has been prepared by Mr. L. C. Ball. Yorkey's Gold Field lies in an area of slates assigned with doubt to the Gympie (permo-Carboniferous) formation, with intrusive masses of granite and diorite, and the auriferous quartz reefs occur in or adjacent to the diorite. The other districts referred to are in the prospecting stages. A report on the west coast of the Cape York Peninsula and on some islands of the Gulf of Carpenteria has been drawn up by Mr. C. F. V. Jackson. Interesting particulars and photographic views are given of

this little known region, including notes on the mangrove trees and their influence on the coast line. The gold-field of Horn Island is described, the reefs occurring in porphyritic granite. The works are now abandoned, but apparently they were started before adequate investigations had been made, and even now it is doubtful whether the trials were exhaustive.

WE have received a copy of the illustrated catalogue of chemical apparatus and laboratory fittings supplied by Messrs. Max Kaehler and Martini, of Berlin, W. The catalogue runs to 500 pages, and will be sent post free to schools and colleges where there are chemical laboratories. The sole agent for the United Kingdom is Mr. S. Bornett, 62 King William Street, London, E.C.

PROF. WYNDHAM R. DUNSTAN, F.R.S., was recently appointed by the Board of Trade to be director of the Imperial Institute, and one of the results appears to be the publication, as a supplement to the *Board of Trade Journal*, of a "Bulletin of the Imperial Institute." The first issue of the bulletin contains much useful information as to the experiments and inquiries which have been carried out in the scientific and technical department of the Institute. Reports on the following investigations, amongst others, are included:—poisonous fodder plants and food grains; analyses and examinations of coal from Trinidad; kaolin from St. Vincent; tin ore from the Bautshi tin fields, Northern Nigeria; fibres from Sierra Leone and Brazil; and nuts from British Honduras and Portuguese East Africa. The second part of the bulletin consists of general notices prepared by the scientific department on a variety of questions, as different as the chemical analysis of gutta-percha as a guide to its cultivation and valuation, and cotton cultivation in Asia Minor. The work of the scientific and technical department is chiefly initiated by departments of the Governments of India and the Colonies. Arrangements have been also made by the Foreign Office whereby British Consuls may transmit for investigation such natural products of the countries in which they are appointed to reside as are likely to be of use to British manufacturers and merchants. Materials are first chemically investigated in the laboratories of the department, which includes a staff of skilled assistants, and are afterwards submitted to technical trials by experts, and finally are commercially valued. Manufacturers, and dealers in natural products, ought to be keenly alive to the advantages to be derived from work and inquiries of this character.

THE additions to the Zoological Society's Gardens during the past week include an Indian Elephant (*Elephas indicus*, ♀) from India, presented by the Maharaja of Benares; a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mr. J. R. E. Stansfeld, D.S.O.; a Crested Porcupine (*Hystrix cristata*), a Black-backed Jackal (*Canis mesomelas*), a Puff Adder (*Bitis arietans*), a Cape Bucephalus (*Dispholidus typus*), a Smooth-bellied Snake (*Homalosoma lutrix*) from South Africa, presented by Mr. Barry McMillan; two Puff Adders (*Bitis arietans*) from South Africa, presented by Mr. A. W. Guthrie; two Black Lemurs (*Lemur macaco*) from Madagascar, a New Zealand Owl (*Ninox novae-seelandiae*), four Variegated Sheldrakes (*Tadorna variegata*) from New Zealand, five Nutmeg Fruit Pigeons (*Myristicivora bicolor*) from Moluccas, six Nicobar Pigeons (*Caloenas nicobarica*) from the Indian Archipelago, a Glossy Calornis (*Calornis chalybeus*), a Hamadryad (*Naia bungurus*) from India, seven Large Andaman Parrakeets (*Palaeornis magnirostris*), an Andaman Starling (*Poliopsar andamanensis*), six Andaman Teal (*Querquedula albigularis*) from the Andaman Islands, two Canadian Cranes (*Grus canadensis*), four Prickly Trionyx (*Trionyx spinifer*) from North America, four Ceylonese Terrapins (*Nicoria trijuga*) from Ceylon, two Adanson's Sternotheres (*Sternothoerus adansoni*) from West Africa, deposited; a Brush Turkey (*Talegalla lathami*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY:—

1. 10h. 40m. Minimum of Algol (β Persei).
5–6. Venus very near Regulus (α Leonis).
9. 8h. 4m. to 9h. 11m. Moon occults ρ' Sagittarii (mag. 3·9).
„ 15h. Venus at greatest elongation, 45° 30′ E.
15. Venus. Illuminated portion of disc = 0.459 of Mars = 0·873.
20. 13h. 56m. Moon in conjunction with Aldebaran (α Tauri).
21. 12h. 23m. Minimum of Algol (β Persei).
23. Mars 1½° N. of Spica (α Virginis).
24. 9h. 12m. Minimum of Algol (β Persei).
26. 8h. Moon in conjunction with Pallas. Pallas 0° 47′ N.
29. 20h. Saturn in opposition to the sun.
30. Uranus ½° N. of 51 Ophiuchi (mag. 4·9).

NEW COMET, 1903 *c*.—A Kiel Centralstelle telegram announces that M. Borelly, observing at Marseilles, discovered a new comet, 1903 *c*, on June 21. Its position for 11h. 36·5m. (M.T. Marseilles) on June 21 was

R.A. = 21h. 52m. 52s., Dec. = 8° 10′ south,

and its daily movements in R.A. and Declination are −28s. and +44′ respectively.

The telegram states that a nucleus and a tail have been observed, but it does not state the magnitude of the object.

A later telegram states that Herr Wirtz, Strasburg, observed this comet at 22h. 8·8m. (M.T. Strasburg) on June 22, and determined its position as follows:—

R.A. = 21h. 51m. 53·73s.
Dec. = 7° 17′ 11″ south.

PHOTOGRAPHIC OBSERVATIONS OF COMET 1902 III.—Prof. Sykora, of Jurjew, has communicated to No. 3871 of the *Astronomische Nachrichten* the results of the photographic observations of Comet 1902 iii. made by him during September and October of last year.

Reproductions of drawings made from the photographs show that on September 26 the comet possessed two tails of Bredichin's second and third types respectively, and the measurements showed that the longer tail was about 2° in length. On October 7 this length was increased to 3°, and the tail was more like Bredichin's first type, whilst the shorter third-type tail had decreased in length. On the photograph taken on October 9 this difference was further accentuated.

THE MIRROR OF THE CROSSLEY REFLECTOR.—Dr. G. Johnstone Stoney writes to correct a misapprehension referring to the mirror of the Crossley reflector in use at the Lick Observatory. The figuring of this mirror is usually attributed to the late Dr. Common, and has been ascribed to him in these columns (pp. 132, 162). It appears, however, from a correspondence between Mr. J. Gledhill and Prof. Campbell that Mr. Crossley's gift to the Lick Observatory included two mirrors, described as A and B, essentially of the same diameter and focal length. One of these, B, was refigured by Sir Howard Grubb, and was sent to America as it came from his workshop. "It is the B mirror," Prof. Campbell states, "which has been used in all the work with the Crossley Reflector at the Lick Observatory." Dr. Stoney adds:—"In any enumeration of noteworthy instruments made by Dr. Common, it would appear desirable to include the very remarkable flat mirrors of large size which he produced of late years, some of them for the cœlostats of the Joint Solar Eclipse Committee of the Royal and Royal Astronomical Societies. The production of

optically flat mirrors of such size and so great perfection was a very great achievement."

RADIANT POINTS OF JULY AND AUGUST METEORS.—A paper by Mr. Denning in No. 3874 of the *Astronomische Nachrichten* describes the meteor showers which occur about the same time of the year as the splendid Perseid shower, and it gives, in tabular form, the radiant points of more than one hundred showers that have been observed at Bristol, during 1876–1902, in the months of July and August, dividing the epochs of appearance into three periods, viz. July 6–16, July 20–August 16, and August 19–25. Many of the displays are feeble, and a prominent feature of these is that they appear for a long period from the same fixed radiant.

The Perseid swarm varies greatly in intensity; at some apparitions as many as 150 to 200 shooting stars are observed per hour, whereas at other appearances the hourly rate may decline to 20 or 30. From a careful survey of the records, Mr. Denning thinks that there is evidence of this shower having a periodicity of between 104 and 123 years. The maximum is now reached on the morning of August 12 or 13.

SUN-SPOTS AND TERRESTRIAL TEMPERATURE.—In discussing the statement recently made by M. C. Nordmann in its application to the temperatures observed at the Jacob camp (Guadeloupe), M. Alfred Angot finds that approximately the same law holds good, and may be represented by the formula

$$t = t_0 + ar,$$

where t is the actual temperature, r is Wolf's frequency number, and t_0 and a are constants for each station, a being a negative quantity. On calculating the temperatures for the Jacob station from this formula, first determining the constants for that place, it is found that they vary but slightly from the observed values, the mean variation being $\pm 0^\circ.06$ C., and M. Angot suggests that an analysis of the annual variations at a number of stations might reveal the presence of further periodical variations (*Comptes rendus*, No. 21).

THE SATELLITES OF SATURN.—*Bulletin* No. 34 of the Lick Observatory contains the results of a second series of observations of the satellites of Saturn made by Mr. W. J. Hussey of that observatory.

Mr. Hussey measured the position angles and distances of each satellite in respect to one of the others, and gives a table containing all the details of each observation; he concludes from estimations of their respective light values that Mimas is probably larger than Hyperion, and, from his measurements, that the generally accepted diameter of Titan is undoubtedly too large; 2500 miles is, according to him, a much nearer approximation to the true value than the values given in most text-books.

THE ROYAL SOCIETY CONVERSAZIONE.

MANY of the objects on view at the Royal Society conversazione on Friday last were shown at the gentlemen's conversazione held on May 15, and have already been described in these columns (p. 59). There was, however, a number of additional exhibits illustrating methods and results of recent work in many branches of science, and these are mentioned below.

The condensation of the radio-active emanations of radium and thorium by liquid air formed the subject of an exhibit by Prof. E. Rutherford, F.R.S., and Mr. F. Soddy. The radio-active emanations of thorium and radium appear to be the residues of the thorium atom and radium atom respectively after the heavy positively charged particles, known as the "α rays," have been projected. They have all the properties of inert gases of the argon family, and diffuse away from the radium and thorium compounds producing them. They can be condensed at the temperature of liquid air, and are again volatilised on raising the temperature. Their actual quantity is almost infinitesimally small, being quite invisible and unweighable, but their presence can be detected by their property of radio-activity.

A method for the rapid determination of the specific gravity of blood, taken from a single drop, was shown by Prof. W. J. Sollas, F.R.S. A fluid heavier than the blood (chloroform and benzole sp. gr. 1·07), and another lighter (benzole and chloroform sp. gr. 1·04), are introduced into a tube, the heavier first, so that the lighter, added subsequently, floats upon it. The two fluids mix by diffusion so as to produce a column in which the specific gravity varies continuously from a higher to a lower value upwards. A drop of blood obtained from a pin prick is then added, and sinks in the column until it reaches a level where the specific gravity is identical with its own. Two glass floats of known specific gravity are now introduced, one of higher and the other of lower specific gravity than the blood. The distances of these, when floating in the column, from the drop of blood are proportional to the difference in specific gravity.

Mr. J. Y. Buchanan, F.R.S., exhibited a copper sphere and brass tube in illustration of an effect produced by the momentary relief of great pressure. Experiments were made during the cruise of the *Challenger* and on board the *Princess Alice*. The copper sphere contained a glass spherical flask of about 1½ inches in diameter hermetically sealed, and the sea water had free access through the two holes at the poles. The brass tube contained a glass tube of 50 cubic centimetres in capacity, hermetically sealed, and the sea water had free access at both ends of the brass tube. The brass tube was sent to a depth of 3000 metres, and at some, probably less, depth the internal glass tube gave way to the pressure and collapsed suddenly. The enclosing brass tube was pinched up by the external pressure. The experiment shows that, in the time, it was easier to pinch the envelope of brass than to shove in the plugs of water at both ends. The copper sphere was sent first to 3000 metres, but was pulled up without showing any effect. It was then sent to 6000 metres, and the internal glass flask collapsed at some depth between 3000 and 6000 metres, and the creasing which is visible on the copper sphere was produced. These experiments, whether made with the copper ball or with the brass tube, furnish striking demonstrations of the importance of the element of *time* in all physical considerations.

Photographs of the paths of aërial gliders were shown by Prof. G. H. Bryan, F.R.S., and Mr. W. E. Williams. These photographs were taken by attaching a piece of magnesium wire to gliders of cardboard, and show the path taken during their descent through the air. By fixing a rotating wheel in front of the camera so as to give a series of exposures instead of a continuous exposure, dotted traces were obtained, the distance between the dots enabling the velocity at different points to be compared.

The solar disc in monochromatic (K) light was exhibited by the Solar Physics Observatory, South Kensington. The glass positive and negative shown was a specimen of one of the trial plates taken for adjustment of the new photo-spectroheliograph. Large belts of prominences could be seen stretching across the solar disc.

The Solar Physics Observatory also exhibited photographs of the spectrum of lightning. The spectra were secured by Dr. William J. S. Lockyer on the early morning of May 31. Small cameras were employed fitted with Thorpe's transparent gratings in front of the lenses.

A reproduction of the hydraulic organ of the ancients was shown by Mr. John W. Warman. This instrument, originally invented by Archimedes about 250 B.C., has furnished a problem for at least 600 years, and has been the subject of endless speculation. The only real difference between the hydraulic and the ordinary or "pneumatic" organ is that, in the former, the wind-pressure is derived from the weight of an annular mass of water, instead of from the loaded top of a folded air-bellows.

Mr. W. N. Shaw, F.R.S., had on view the July number of the Monthly Pilot Charts of the North Atlantic and Mediterranean, issued by the Meteorological Council. The chart was exhibited to show the modifications introduced since the commencement of the series in April, 1901.

Bactericidal emanations from radium were demonstrated by Mr. Henry Crookes, who also showed photographs of a box of instruments, (*a*) taken by ordinary Röntgen rays, (*b*) taken by radium emanations at a distance of eighteen inches.

Other subjects of exhibits belonging to the physical sciences were:—photographs illustrative of the Coronation Naval Review, 1902, Dr. W. J. S. Lockyer; the Cooper-Hewitt mercury vapour lamp of the British Westinghouse Electric and Manufacturing Company, Ltd., by Prof. Ernest Wilson; an automatic mercury vacuum pump, by Dr. S. R. Milner; (1) stereoscopic fluoroscope, (2) stereoscopic X-ray photographs, Mr. J. Mackenzie Davidson; detonation of small shells, Dr. O. J. Silberrad; (1) apparatus for obtaining monochromatic illumination with the microscope, (2) a new turbidimeter, for determining the turbidity of water, by Mr. Charles Baker; controlling and regulating spark discharges, experiments in illustration, by Mr. Alfred Williams.

Prof. E. B. Poulton, F.R.S., illustrated the protective resemblance of butterflies to dead leaves and fragments of dead leaves. A resemblance to entire dead leaves with midrib, traces of oblique veining, and often attacked by fungi, is found in many genera of tropical butterflies. Holes, when represented, appeared to have been gnawed by insects, &c. There are three stages in the representation of such holes:—(1) by opaque strongly reflecting "body colour"; (2) by transparent windows; (3) by actual apertures. In the Holarctic region, with its deciduous trees, a genus (Polygonia = Grapta) which is defended by the same kind of concealment resembles, not entire leaves, but weather-beaten and ragged fragments, and it is not a gnawed hole which is represented on the butterfly, but a curved crack due to chemical and mechanical changes in a dead leaf fragment.

The director, Royal Botanic Gardens, Kew, showed three interesting instances of plant adaptations, namely, (1) a sensitive orchid (*Masdevallia muscosa*) from New Grenada. The lip closes when an insect lights on it; the insect, in crawling out, is compelled to carry the pollen masses away with it. (2) A case of commensalism (*Dischidia rafflesiana*) from Java. Leaves become converted into bags which ants fill with soil; the plant sends roots into the "flower pots" thus formed. (3) A possible case of protective mimicry (*Mesembryanthemum Bolusii*) from South Africa. The fleshy leaves simulate the lichen-covered fragments of rock amongst which they grow.

An exhibit by Dr. D. H. Scott, F.R.S., and Prof. F. W. Oliver illustrated Lyginodendron and its seed Lagenostoma. Lyginodendron is a characteristic member of the Palæozoic group Cycadofilices, a group recognised as occupying an intermediate position between ferns and gymnosperms. Hitherto no certain knowledge of the reproductive organs of these plants has been available. A reinvestigation of the detached Coal-measure seeds belonging to Williamson's genus Lagenostoma has furnished evidence which leads to the conclusion that one of them (*Lagenostoma Lomaxi*) was borne by Lyginodendron.

Fossil vertebrata from the Fayûm, Egypt, were exhibited by the director, British Museum (Natural History). The most important of the specimens were portions of the skull of the remarkable horned mammal, Arsinoïtherium, from the Upper Eocene. Specimens of the upper and lower dentition of the primitive elephants Palæomastodon and Mœritherium were also exhibited; these showed that the teeth are comparatively simple, and that the premolars and molars are in use simultaneously as in the ordinary mammal. Remains of the elephant and antelopes associated with flint implements from the lake beds of the lake Birket-el-Kerun were also shown.

A chart representing the first results of experiments on the migrations of plaice in the North Sea was shown by the Marine Biological Association. The distances travelled by some of the fishes have been very great, amounting in one case to 160 miles in six weeks. The Association also had on view a new British species of the Polychæte family Sabellaridæ, and living representatives of the Plymouth marine fauna.

The following were also among the objects on view:—mounted specimen of newly-born Indian elephant (*Elephas maximus*), born in the Zoological Society's Gardens, showing the hairy nature of the skin, as in the mammoth, by the director, British Museum (Natural History). A series of spear-heads, manufactured by the existing Aborigines of the north-west territories of Western Australia, by Dr. Henry Woodward, F.R.S. Remains of fossil mammals from an ossiferous cavern of Pliocene age at Doveholes, near Buxton, Derbyshire, by Prof. W. Boyd Dawkins, F.R.S. Colour photographs of living insects to illustrate protective coloration and resemblance, by Mr. F. Enock. (1) Tail feathers from a common male pheasant, illustrating sexual transformation of plumage; (2) a wild duck bred in captivity showing a converse change, by Mr. S. G. Shattock and Mr. C. G. Seligmann.

During the evening Prof. E. B. Poulton gave an account of the discoveries of Mr. Guy A. K. Marshall upon the wet season and dry season forms of Rhodesian butterflies. Mr. Marshall has proved, in three cases, by breeding the one from the other, that butterflies which are entirely different in colour, pattern, shape, relation of upper side to under side of wings, and even habits, and the selection of a certain type of country, are only the summer and winter forms of one species. The winter forms are always the better concealed in these cases, probably because the butterfly passes a much larger proportion of its life in a state of complete repose.

The Bioscope Company gave a lantern demonstration illustrating the scientific and educational applications of the bioscope.

THE ENGINEERING CONFERENCE.

LAST week the Institution of Civil Engineers held the bi-annual engineering conference for the present year, under the presidency of Mr. John Clarke Hawkshaw, president of the Institution.

The proceedings commenced on the evening of Tuesday, June 16, when Mr. W. H. Maw, past-president of the Institution of Mechanical Engineers, delivered the eleventh "James Forrest" lecture in the theatre of the Institution, his subject being "Some Unsolved Problems in Engineering." We published an abridgment of Mr. Maw's address last week (p. 163). On the following day, Wednesday, June 17, the chief business of the meeting commenced, and was continued over the Thursday and Friday following. The conference was divided into seven sections, the members of which met in various rooms near the Institution house in Great George Street. These sections were as follow:—Section i., railways, chairman, Sir Guilford Molesworth; section ii., harbours, docks and canals, chairman, Sir Leader Williams; section iii., machinery, chairman, Dr. Alex. B. W. Kennedy; section iv., mining and metallurgy, chairman, Mr. E. P. Martin; section v., shipbuilding, chairman, Sir John I. Thornycroft; section vi., waterworks, sewerage and gasworks, chairman, Sir Alexander Binnie; section vii., applications of electricity, chairman, Mr. Alexander Siemens.

Before proceeding to the various section rooms, members of the congress assembled in the theatre of the Institution of Mechanical Engineers to hear an introductory address from the president of the Institution of Civil Engineers, Mr. J. C. Hawkshaw. The address alluded to the work done at past conferences, and subsequently referred to the Engineering Standards Committee, which had been organised by the Institution in conjunction with various other technical bodies. The subject of the education and training of engineers was also touched upon, and in connection with the Admiralty scheme of training, the president pointed out that a similar plan of operations was devised by the Institution for the admission of students and associate members. Referring to the pollution of the town by smoke, the president said that "neglect to deal with it is yearly costing the growing population of London a large sum, and a Royal Commission had been appointed to inquire into the subject." The problems of locomotion and transport, timber supplies, and motor-car traffic were also dwelt upon briefly.

RAILWAYS.

The section devoted to railways met on the first and second days of the meeting, five papers being read in all. The first paper was on "The Assimilation of Railway Practice as Regards Loads on Bridges up to 200 feet Span," the subject being introduced by Mr. A. Ross. It was pointed out that it was undesirable to carry standardisation

to such an extent as might tend to arrest advancement in type or design, although it was of the utmost importance that uniformity should be arrived at with regard to the loads to which such structures might be subjected. In the discussion it was suggested that loads on bridges were nearing a limit, as electric traction would probably come into use, and this would do away with the need for the heavy steam locomotive.

In a contribution on "The Design of Permanent Way and Locomotives for High Speeds," by Mr. J. C. Inglis, it was pointed out that the increase in train mileage of British railways was mostly on long distance traffic, which meant heavy trains with heavy axle loads hauled at a relatively high speed. For express running, up to 60 miles an hour, no curves should be less than 40 chains radius. Heavy rails gave smoother running, and 90 to 100 lbs. per yard was often the practice. Four-coupled engines, with the front wheels coupled and a bogie under the foot-plate, formed an undesirable class of engine for high speed running, whilst engines with single drivers, and only one axle in front and one behind, were likewise unsatisfactory, and plunged considerably, even on good roads. Equalising levers had much to recommend them, and recent practice had been in the direction of raising the centre of gravity of the locomotive.

Mr. W. J. Cudworth read an interesting paper on "Automatic Signalling," giving particulars of applications that had been made on the London and South-Western Railway and on the North-Eastern Railway. Mr. Jacomb-Hood, in the discussion, said he was convinced that automatic signalling had a great future before it.

Lieut.-Colonel Yorke, R.E., introduced the subject of "The Organisation and Administration of an American Railway," which he dealt with in some detail. He advocated the separation of the traffic or commercial department from the operating or working department, as followed in America, although unusual in this country. The value of keeping accurate statistics was dwelt upon during the discussion.

"The Relative Advantages of Overhead, Deep-level, and Shallow Subway Lines for the Accommodation of Urban Railway Traffic" was the subject brought forward by Mr. S. B. Cottrell, who discussed the respective advantages and disadvantages of the different systems.

HARBOURS, DOCKS, AND CANALS.

This section met on the first and last days of the congress, Wednesday and Friday, and five papers were read in all. The first paper was on "Dredging in New South Wales," Mr. C. W. Harley being the author. He pointed out that rivers were the natural means for conveying produce, and the New South Wales Government had expended considerable sums on improving its navigation. Particulars of the extensive plant that was used for this purpose were given.

The second paper on the list was "Dredging, with Special Reference to Rotary Cutters," by Mr. J. H. Apjohn. The value of hydraulic dredgers, and the results achieved on the bar of the Mersey and other rivers, were first referred to. In dealing with rotary cutters, the author pointed out that the form of the blades and the angle at which they were set, whether they were straight or spiral, and the openings between them at the bottom, were the points to be determined. Different descriptions of material needed different forms of cutters. These two papers were discussed together, Sir Leader Williams, Prof. Vernon Harcourt, Mr. Wheeler, Mr. Matthews, and others speaking. The question of "Foreshore Protection and Travel of Beaches" was next taken, the subject being introduced by Mr. W. T. Douglass. This matter was discussed at a conference at Norwich, held last January, and the author dealt with the various points raised in connection with the subject, such as direction of current, depth of water, effect of flood tides on the travel of the beach, angle and length of groynes, &c. In the course of discussion, Mr. Matthews pointed out that often the value of land reclaimed was not equal to the cost of saving it.

The other papers read in this section were "The Modern Equipment of Docks, with Special Reference to Hydraulic and Electric Appliances," by Mr. Walter Pitt; and "Recent Improvements in Canal Engineering," by Mr. Gerald FitzGibbon.

MACHINERY.

In the machinery section sittings were held on the Wednesday and Thursday. The first subject was introduced by Mr. Archd. P. Head, and was on "The Speed of Overhead and other Cranes as a Factor in the Economic Handling of Material in Working." The author favoured continuous current for crane work at 220 to 500 volts. He preferred this to alternate current on account of the greater starting torque and acceleration which it gave; although alternating current motors were efficient at full loads, they could only have a strong starting torque at the expense of efficiency. Continuous current also admitted of easier regulation, was cheaper in wiring, and could be stored in batteries to equalise a variable load. Series-wound motors automatically ran faster with lighter loads, and should be used coupled permanently to the gear. They could withstand 100 per cent. overload for short periods, and higher overloads momentarily, without damage. Motors running continuously with clutch connections to the gearing should be shunt-wound. Quick stopping could be achieved by an electric brake working on the armature shaft, operated by a weight or spring, and taken off by a solenoid in series with the motor. A somewhat lively discussion followed the reading of Mr. Head's paper, Mr. Tannett Walker and Mr. Ellington advocating the use of hydraulic cranes, although the latter allowed that electricity was the best source of motive power for overhead travellers.

A valuable paper by Mr. H. J. Marshall, "Gauges and Standards as Affecting Shop and Manufactory Administration," followed. The subject is one which does not well lend itself to being abstracted in a few words, but Mr. Marshall's paper is the more valuable because it represents actual experience in large works.

Mr. H. A. Humphrey's paper on "Internal Combustion Engines for Driving Dynamos" was also one of considerable interest, and attracted a good many of the electrical engineers from section vii. The author dealt with the large gas-engines which have quite recently come into use, and the design of which, unfortunately, we largely owe to the Continent, where the application of blast furnace gas to internal combustion engines has given an impetus to this branch of industry. The author stated that there were about fifty firms manufacturing large gas engines of 200 horse-power and upwards. The engines completed or on order numbered 515, having an aggregate capacity of 328,065 horse-power; of these, 398 engines were for dynamos, and gave collectively 206,805 I.H.P. The gas producer and gas engine constituted the cheapest means of generating electric power, where coal was the basis of energy, and the gas engine had proved quite trustworthy for driving alternators in parallel. He considered that ultimately the gas engine would entirely take the place of steam plant in large central electric stations. A long discussion followed the reading of this paper, in which the views of the author were upheld by some speakers. Dr. Kennedy (who occupied the chair), however, said that before he advised the application of internal combustion engines for the generation of electrical energy he would like to feel more confidence, or have more experience on the subject. Mr. Crossley and Dr. Hopkinson, who both spoke, gave some remarkable figures, showing the advantage of gas engines over steam engines in regard to economy.

"The Use of Petrol Motors for Locomotion" was the subject introduced by M. E. Sauvage, the well-known French locomotive engineer, who gave in detail the points that should be observed in designing a successful petrol motor. In the discussion, Mr. Aspinall and other locomotive engineers pointed out that though the single unit vehicle had advantages, and appeared very attractive at first sight, practical considerations militated against it, and where, in the past, the system had been tried, it had been abandoned sooner or later.

The chief feature in this section was the last paper read, which was on "Apprenticeship in Engineering Education," by Prof. J. D. Cormack. The subject is too long and too important to treat in a brief report of this nature. Prof. Cormack merely set forth the chief aspects of the question, without pretending to arrive at any conclusion,

leaving the latter task to the speakers in the discussion; of these there were no less than twenty-five. They included Sir W. H. White, Prof Kennedy, Colonel Crompton, Captain Sankey, Profs. Ayrton, Burstall and Capper, the Hon. R. C. Parsons, and Messrs. D. Drummond, A. F. Yarrow, E. B. Ellington, Bertram Hopkinson and Mark Robinson. Most diverse opinions were expressed by the various speakers, but it may be said generally that some system in which a college course would alternate with practical experience, in periods of greater or less duration, received acceptation. Sir William White, in closing the discussion, gave a promise that the matter would be considered by the council of the Institution of Civil Engineers, which would take into consideration what had been said in the section, as well as the proceedings before the Institution of Mechanical Engineers and the Institution of Naval Architects, both of which had had presented to them papers on this subject by Prof. W. E. Dalby, who recently made a tour in America and on the Continent to study this question.

MINING AND METALLURGY.

Seven papers were read in this section. The first taken was by Sir Thomas Wrightson, Bart., M.P., and Mr. John Morison, the subject being "Notes on Percussive Coal Cutters." Details of the machinery were given, the authors arriving at the conclusion that in America machine coal-cutting had been successful, but in this country, up to the present, almost the opposite experience had been the result of the adoption of machinery, the economy, except in special cases, being doubtful.

"Recent Improvements in Gold-mining Machinery on the Rand," by Mr. A. E. T. Lees, followed. He dealt with the labour difficulty and its effect on the introduction of labour-saving devices. Considerable progress has recently been made in surface works, as well as certain improvements in mining machinery generally.

Mr. J. H. Harrison read a paper on "Equalising the Temperature of the Blast for Blast-furnaces, and its Effect on the Melting Zone." He gave particulars of the practice followed in America for preventing "scaffolds."

"Notes on Steam-driven and Gas-driven Blowing Engines" were contributed by Mr. Tom Westgarth, who had no hesitation in saying that the gas engine generally was more suitable for blast-furnace work, provided always that the gas saved by the use of the gas engine could be readily employed.

The remaining three papers read in this section were:—"The Continuous Method of Open-hearth Steel-making," by Mr. B. Talbot; "Alloys of Iron, Nickel and Manganese," by Mr. R. A. Hadfield; and "The Dangerous Crystallisation of Mild Steel and Wrought Iron," by Prof. J. O. Arnold.

SHIPBUILDING.

Section v. had five papers before it. The first was by Mr. A. F. Yarrow on "The Comparative Merits of Drilling and Punching in Steel for Shipbuilding." The author gave particulars of the British Admiralty regulations, which require drilling in place of punching for light vessels. He had found by experience that this was a wise provision, although it had been objected to by some contractors. In the discussion which followed, it was allowed that a drilled hole was better than a punched hole for light vessels, such as torpedo craft. For merchant ships, however, the greater expense of the drilling might be objected to.

Mr. John List read a paper on "Screw Shafts," pointing out the severe effects set up in them by racing in light vessels. He referred to the growing use of nickel steel for propeller shafts.

Mr. A. E. Seaton also read a paper on "The Modern Express Steamer for Short Passages," whilst Prof. A. Rateau dealt with "Steam Turbines." Mr. H. H. West contributed a paper on "Harbour Dues and Charges."

WATER-WORKS, SEWERAGE AND GAS-WORKS.

Five papers also were read in this section. The first was by Mr. G. T. Beilby on "Smoke Abatement." The author looked forward to the spread of the internal combustion engine and electric transmission of power to produce a better state of the atmosphere in large towns. He also considered that the firing of steam-boilers with washed gas would prove advantageous.

The next paper read was by Dr. S. Rideal, and was on "Coal-gas Standards." The subject is not one that lends itself to compression. The same may be said of Prof. Percy F. Frankland's paper on "The Bacterial Treatment of Water and Sewage." The other papers read in this section were:—"Steam Turbine-driven Centrifugal Pumps for High Lifts," by Mr. C. W. Darley; and "The Raising of Water by Compressed Air," by Mr. Percy Griffith.

APPLICATIONS OF ELECTRICITY.

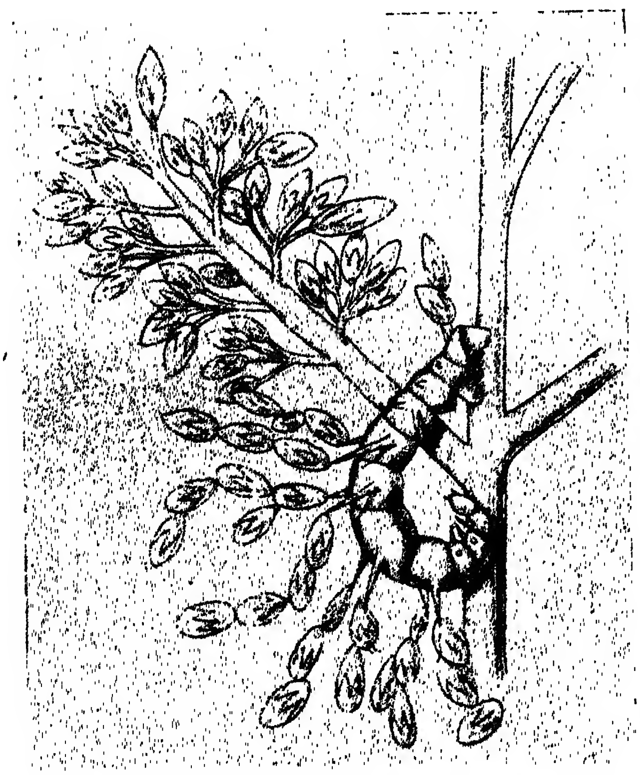
Five papers were read in section vii. The first was on "Wireless Telegraphy," introduced by Mr. E. A. N. Pochin, who gave a review of the principles involved in this subject and of recent developments. Among important facts which have lately been established are:—(1) up to considerable ranges earth-curvature is not a fatal obstacle, but hills may exercise a serious influence; (2) the ether exhibits what we may provisionally call a variable transparency to Hertzian waves, sunlight being an important factor. With regard to both these phenomena, it is probable that certain wave-lengths offer special advantages, whilst the second affords a faint clue to the relative share of earth and ether in transmission. Amongst problems, that of isolation is undoubtedly the most important, and in this direction two methods have been employed, which may be termed respectively syntonic and optical methods, both of which were described as regards performance and promise. During the discussion which followed, Mr. Gavey expressed the opinion that syntony in installations of wireless telegraphy of from 60 to 100 miles could be established, and maintained with certainty and regularity; but for long distances transmission was uncertain, owing to causes which were not apparent. The remaining papers read in this section were on the "Applications of Electricity to Driving Carriages in Towns," by Lieut.-Colonel R. E. B. Crompton, C.B.; "The Transmission and Distribution by Single-phase Alternating Current," by Mr. E. W. Monkhouse; "High-speed Electric Traction on Railways," by J. W. Jacomb-Hood; and "The Position and Protection of the Third Rail on Electric Railways," by Mr. W. E. Langdon.

NEW CASE OF PROTECTIVE MIMICRY IN A CATERPILLAR.

IT is well known that the larvæ of many insects, such as those of the case moths, clothes moths, caddis flies, tortoise beetles, and the masked bug, construct for themselves cases or artificial coverings either for protection or concealment, and a new and somewhat remarkable instance is described by Mr. R. Shelford, the curator of the Sarawak Museum, in the *Zoologist* for May. We are indebted to the publishers for the accompanying illustration of the caterpillar described.

On May 16, 1900, a native collector brought in a quantity of a Spiræa-like plant, intended for the food of butterfly-caterpillars. It bore numerous pale green cymose inflorescences which were still in bud, and presently one of the branchlets was noticed to be moving. This proved to be due to the presence of a small Geometer caterpillar (only 9 millimetres in length) covered with buds from the inflorescence on which it was feeding. This "bore the following spine-like processes, a dorsal pair on the 4th segment, a dorso-lateral pair on segments 5, 6 and 7, a lateral pair on the 8th segment, and a short dorsal pair on the 11th; there were also some small tubercles in the positions shown in the accompanying sketch." To these spines strings of buds, connected by silk, were fastened in a similar manner, and when the green buds faded, or were removed, they were immediately replaced by fresh ones. "A bud would be shorn off with the mandibles, then held in the two front pairs of legs, and covered all over with silk issuing from the mouth of the larva; the larva then twisted round the anterior part of the body, and attached with silk the bud to one of the spinous processes, and another bud would then be attached to this, and so on, until a sufficiently long string (generally three or four buds) was made, when operations on another spine would be com-

menced." The larva fed on the buds of the inflorescence, scooping out the interior, and (when not hurried) using the empty shells in preference to whole buds for its covering. "When irritated, the larva curled up in the attitude represented in the sketch, and it remained in this position for fifteen or twenty minutes." At other times it would sway about, looking like a branchlet blown by the breeze. The larva spun up on May 28, forming a silk cocoon covered with green buds, but it was, unfortunately, destroyed by ants, and as no other specimen could be discovered, it is



supposed that, as is well known to be frequently the case with specially protected insects, the species must be very rare. The perfect insect is, of course, at present unknown.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Harkness geological scholarship has been awarded to Mr. R. H. Rastall, Christ's, and the Wiltshire prize in palæontology to A. Blackie, Peterhouse, and H. H. Hodgson, Trinity, equal.

The Museum of Zoology has received an important addition through the bequest of the late Mr. T. E. Buckley, of Trinity College. The collections include some 440 volumes of books, and about 400 birds.

In the natural sciences tripos, part i., thirty men and one woman gain first classes. In part ii. thirteen men and one woman appear in the first class.

The Raymond Horton-Smith prize for the best M.D. thesis of the year is awarded to the Hon. G. H. Scott, Trinity.

At St. John's College the Hockin prize for experimental physics is gained by Mr. J. H. Field, late Lieut. R.E. The Adams memorial prize in astronomy is awarded to Messrs. Gold and Phillips, equal. The Hutchinson studentship for research in botany goes to Mr. R. P. Gregory, University demonstrator.

DR. A. F. DIXON, professor of anatomy in University College, Cardiff, has been appointed to the chair of anatomy in Dublin University, lately held by Prof. Daniel Cunningham.

MR. J. STUART THOMSON, lecturer on biology at the Municipal Technical School, Plymouth, has been appointed to the post of assistant to the Government Marine Biologist at the Cape of Good Hope.

DR. K. J. P. ORTON, demonstrator in practical chemistry at St. Bartholomew's Hospital Medical School, has been appointed professor of chemistry at the University College of North Wales, Bangor, in succession to Dr. Dobbie.

THE Massachusetts Institute of Technology has established a laboratory of physical chemistry to be opened in September, which is to be devoted exclusively to research work. The laboratory is to be under the directorship of Prof. A. A. Noyes, with whom will be associated Profs. H. M. Goodwin and Willis R. Whitney. The researches will be carried on in large part by a staff of research assistants and associates working under their direction. Every facility will also be offered to advanced students who wish to carry on investigations in this branch of science.

AN appeal for funds to extend the department of experimental and applied science and natural sciences is being issued by the University of Dublin. It is pointed out that the University of Dublin must either obtain external aid to build and equip laboratories and lecture rooms for physical science, electrical and mechanical engineering, botany and zoology, or teach these subjects under grave disadvantage. A full report, drawn up by a committee appointed by the board of Trinity College to consider the present scientific requirements of the college, shows that a sum of 100,000*l.* is needed to provide for the requirements of the scientific schools of the University. Owing to the generosity of Lord Iveagh, however, the appeal is reduced to a request for an increased income of 2700*l.* The entire capital outlay, 34,000*l.*, is undertaken by Lord Iveagh if the necessary income for upkeep is forthcoming within the next three years.

FOR a long time past the Merchant Venturers' Technical College, Bristol, though a large building, has been inadequate to meet the demands of the increasingly large number of adult day and evening students. Negotiations have, however, just been concluded by which an additional building will become available for the purposes of the college in September next. It is hoped to make provision in this new building for an extensive boot and shoe shop, and for new shops for printers, painters, bookbinders, and plumbers. In order that the new workshops may be fitted up with the latest improvements, the teachers of the college are to visit workshops of the same kinds in other towns. It is hoped also that the local manufacturers interested in the trades in question will be willing to contribute funds or apparatus. The total floor space in the new building will be close upon 12,000 square feet. The space available for the mechanical and the electrical engineering laboratories will be more than doubled. The present small hydraulic laboratory will be replaced by one many times larger, and a new large physical laboratory will be provided. Arrangements are being made to provide as early as the manufacturers can make them a large experimental steam engine, with two additional dynamos and all necessary measuring apparatus, at a cost of about 2000*l.*

THREE months ago, on March 26 (vol. lxvii. p. 500), a note was given of the gifts to science and higher education announced in *Science* for the preceding quarter. Since then the following benefactions have been published in our contemporary:—Harvard University has received two anonymous gifts, respectively 2000*l.* and 10,000*l.*, for Emerson Hall, to be erected for the department of philosophy, for which the necessary 30,000*l.* required has now been obtained; a fund of 2100*l.* has been subscribed to establish a lectureship in memory of Edwin L. Godkin; 2000*l.* for the establishment of a scholarship and 1000*l.* for the Semitic Museum by the will of Jacob A. Hecht; Mrs. John Markoe has given 1000*l.* to establish a scholarship in memory of her son; and the Harvard Club of Chicago has given 1000*l.* to found a scholarship in memory of Dunlop Smith. Mrs. Anderson has given 200,000*l.* to Barnard

College, Columbia University, to purchase the three blocks of land adjoining Columbia College. Mr. Joseph Pullitzer has given 3000*l.* for scholarships to the university. From the will of Dr. Thomas W. Evans, the City of Philadelphia will receive about 800,000*l.* for the "Thomas W. Evans Museum and Institute Society." Mr. John D. Rockefeller has offered to duplicate money raised by Acadia College, in Wolfville, N. S., up to 20,000*l.* before January 1, 1908; he has also offered to pay two-thirds of the cost of a building for the University of Nebraska to be used for social and religious purposes, on condition that the remaining third of the 20,000*l.* be contributed within about a year, and to give Denison College, Newark, Ohio, 12,000*l.* if the institution will raise a like sum by January 1, 1904, for the construction of additional buildings. Chicago Yale alumni give 500*l.* a year for the establishment of four Yale scholarships. Dr. Elizabeth L. McMahon left 1600*l.* to found a scholarship in Vassar College for daughters of deceased physicians. Colby University, Maine, receives 1000*l.* by the will of the late Robert O. Fuller, of Cambridge, Mass. The will of Mrs. Susan Bevier gives 10,000*l.* to the Rochester Athenæum and Mechanics' Institute. Mrs. Helen F. Ackley has left to Wesleyan University a bequest of 400*l.*, the income from which is to be used for the benefit of one or more women students. Mr. Andrew Carnegie has given 50,000*l.* for an extension of the Mechanics and Tradesmen's Institute, New York City. Dr. D. K. Pearsons has given Winter Park, Florida, 10,000*l.*, and Kingfisher College, Oklahoma, 5000*l.* The late Ario Wentworth, of Salem, Mass., left 20,000*l.* to the Massachusetts Institute of Technology. Mrs. Vail, wife of Prof. Vail, has given Hobart College 1000*l.* The late Walter D. Pitkins has bequeathed 2000*l.* to Yale University. Mr. Francis L. Stetson, of New York, has given 5000*l.* to Williams College. Mr. Robert C. Billings has given the same sum to Wellesley College. Mr. Henry Denhart, of Washington, Ill., announces a further gift of 29,000*l.* to Carthage College. He offers 20,000*l.* for the endowment fund providing that the same amount be raised in the college territory, half of the expense of any new buildings erected up to 10,000*l.*, and 5000*l.* cash.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 28.—"On the Adaptation of the Pancreas to different Foodstuffs." Preliminary Communication. By F. A. **Bainbridge**, M.B., M.R.C.P. Communicated by Prof. E. H. Starling, F.R.S.

The author's observations have been made in the hope of determining, first, whether the composition of pancreatic juice (as regards its enzymes) varies in response to the stimulus of different foodstuffs, and, secondly, by what means this adaptation is carried out. The enzyme studied was lactase, which converts lactose into galactose and dextrose, and the degree of inversion produced by the enzyme was estimated by Pavy's method.

It was found that when dogs were fed on milk for two or three weeks, their pancreatic juice contained lactase, whereas the pancreatic juice of adult dogs not fed on milk contained no lactase. It seemed clear, therefore, that a definite foodstuff—lactose—caused the pancreas to secrete an enzyme capable of producing (in the lactose) digestive changes; in fact, the pancreatic juice varied in composition with different diets. It is believed by Pawloff and others that this adaptation is carried out entirely by a nervous mechanism, and that a given food reflexly excites the pancreas to secrete a juice specially adapted for the digestion of that particular foodstuff, and Weinland has adopted this view as regards the lactase of the pancreas.

However, Weinland's observation that lactose injected subcutaneously did not cause the formation of lactase by the pancreas suggested to the author that the intestinal mucous membrane must be concerned in the production of lactase, and that possibly the process was chemical rather than nervous. The author found that when an extract of the intestinal mucous membrane of a dog fed on milk was injected into a second biscuit-fed dog, the pancreatic juice of the latter contained lactase. On the other hand, when a watery extract of the intestinal mucous membrane of a *biscuit-fed* dog was injected intravenously into a second biscuit-fed dog, the pancreatic juice of the latter contained no lactase. These results suggest that, in consequence of the action of the intestinal mucous membrane on lactose, some substance is formed which passes by the blood-stream to the pancreas, where it stimulates the latter to manufacture a specific enzyme-lactase. If this proves to be the case, the whole process of adaptation must be chemical rather than nervous.

"Hydrolysis of Fats *in vitro* by means of Steapsin." By Dr. J. **Lewkowitsch** and Dr. J. J. R. **Macleod.**

Experiments which one of the authors (J. L.) had made with lipase prepared from pig's liver had not led to a higher hydrolysis of cotton-seed oil than 3 per cent. A fresh series of experiments was, therefore, commenced jointly by the authors with steapsin. Preparations of steapsin were obtained by mincing 200 grams of fresh pig's pancreas and triturating it in a mortar with twice the bulk of water. The preparations were not incubated at the body temperature, as previous experiments had proved that steatolytically active preparations had lost considerably in steatolytic power by being kept at 37° C.

The experiments were carried out by triturating in a mortar varying quantities of the steapsin preparations with cotton-seed oil until an emulsion was obtained. Unless the preparation and the oil form a thorough emulsion, no action of the ferment can be expected. If the emulsions are allowed to stand, hydrolysis commences after a few days, and reaches in the course of a few weeks a very considerable amount. Hydrolysis up to 86 per cent. was obtained after a lapse of a few months in the case of cotton-seed oil. Lard has not given so high a percentage of hydrolysis, although the opposite result would have been expected, inasmuch as the consistency of lard favours the state of emulsion.

Steapsin does not seem to produce the reversible action which other enzymes have been shown to exert. So far, small quantities of acid or alkali do not appear to influence the action of the ferment.

The foregoing experiments prove for the first time that it can be demonstrated by the usual quantitative methods of fat analysis that steapsin is a very powerful fat-splitting ferment.

June 11.—"The Measurement of Tissue Fluid in Man." Preliminary Note. By George **Oliver**, M.D., F.R.C.P. Communicated by Sir Lauder Brunton, F.R.S.

The object of this preliminary note is to indicate a method by which the tissue fluid in man may be measured, thus enabling the observer to ascertain the conditions under which it is effused and disposed of.

In the course of some observations made with the view of eliminating tissue fluid as a cause of variability in the samples of blood obtained for examination, the author found that the rolling of a tight rubber ring over the finger from the tip to beyond the interphalangeal joints will, as a rule, considerably raise the percentages of the blood corpuscles and of the hæmoglobin. The author could not arrive at any other conclusion than that the ring not merely empties the vessels, but likewise clears away any tissue fluid present in the skin and subcutaneous tissues. The needle, in puncturing the capillaries, liberates a certain portion of lymph from the areolar tissue which surrounds them, and this dilutes the blood. When, however, both fluids have been dispersed as much as possible by the compression of the firm rubber ring, a puncture made just before removing the ring yields blood *per se*; for the blood instantly returns to the vessels, whereas an appreciable interval must elapse before the lymph reappears, or is exuded afresh. The author therefore inferred that the reading of the difference in the percentage of the corpuscles, or of the hæmoglobin, before and after the use of the ring, provides a measure of the tissue-lymph, and makes the study of the circulation of it in man possible.

This simple method having furnished somewhat unexpected results, the author accepted them at first with reserve; and, for some time, the data were allowed to accumulate, until at last it was quite apparent that they invariably fell into the same order. Inasmuch as the method did not provide results which were exceptional or erratic, or contradictory and unaccountable, trust on it became gradually established by the mere repetition of the observations.

A number of observations have been made on normal subjects leading a quiescent life, with comparative rest of the muscles; and on persons subjected to varying degrees of exercise, and to different temperatures and altitudes. In this note the author limits himself, however, to a statement of results obtained in the former class of subjects only.

The numerous observations which this inquiry necessitated on the corpuscles, and on the hæmoglobin, were made by the hæmocytometer tubes and the hæmoglobinometer, which were described by the author before the Physiological Society some few years ago (see *Journal of Physiology*, Cambridge and London, vol. xix. p. 15), and the specific gravity of the blood was determined by Roy's method. The blood-pressures (arterial, capillary, and venous) were read by the hæmodynamometer (*ibid.*, vols. xxii., xxiii.), and Hill and Barnard's sphygmometer, and Prof. Gärtner's tonometer, were also occasionally used in determining the arterial pressure.

Some of the general conclusions afforded by the observations may be thus epitomised:—

(1) The amount of tissue fluid varies at different times in the course of the day, and each variation is of short duration.

(2) The ingestion of food produces a rapid flow of lymph into the tissue spaces, which in an hour after the meals acquires its maximum development, and then it slowly subsides, and only ceases to be apparent after the lapse of from 3 to 4 hours.

(3) The digestive curve of variation always follows the same general type; the rise being rapid, the acme short, and the subsidence gradual. The variations were observed to follow this well-defined order in all the healthy subjects so far submitted to observation. The curve of variation is, therefore, rhythmical—the wave abruptly rising to an acme and then somewhat slowly subsiding.

The following are two examples:—

Example 1.

	Corpuscles per cent.		Diff.	Percentage of lymph.
Before the meal (breakfast)	99[1] / 103	(4,950,000 per c.mm.) / (5,150,000 ,,)	200,000	4
1 hour after ...	91 / 106	(4,550,000 ,,) / (5,300,000 ,,)	750,000	15
2 hours after ...	94 / 105	(4,700,000 ,,) / (5,250,000 ,,)	550,000	11
3 hours after ...	96 / 104	(4,800,000 ,,) / (5,200,000 ,,)	400,000	8
4 hours after ...	98 / 101	(4,900,000 ,,) / (5,050,000 ,,)	150,000	3

Example 2.

	Corpuscles per cent.		Diff.	Percentage of lymph.
Before the meal (dinner)	99 / 99	(4,950,000 per c.mm.) / (4,950,000 ,,)	None	0
1 hour after ...	91 / 108	(4,550,000 ,,) / (5,400,000 ,,)	850,000	17
2 hours after ...	94 / 106	(4,700,000 ,,) / (5,300,000 ,,)	600,000	12
3 hours after ...	104 / 104	(5,200,000 ,,) / (5,200,000 ,,)	None	0

(4) The amount of lymph is proportionate to the rise of the mean arterial and capillary pressures, and these pressures have been found to follow exactly the same prolonged rhythmical course after the ingestion of food as does the effusion of lymph.

The following example shows the agreement between the blood-pressures and the amount of lymph:—

	Percentage of lymph.	Mean arterial pressure.
Before the meal	None	100 c.mm. Hg.
½ hour after	10	110 ,,
1 hour after...	16	116 ,,
1½ hours after	8	108 ,,
2 hours after	5	105 ,,
3 hours after	None	100 ,,

[1] The figure on the first line represents the percentage of corpuscles before, and the figure on the second line that after, compression of the finger by the rubber ring.

The method devised for observing the capillary pressure is not quite so delicate for the smaller variations as could be wished, and the author hopes to improve it; but it is sufficiently definite to show that the capillary blood-pressure is raised throughout the digestive circulatory disturbance, and especially so at the acme of it, and falls again at the close of it. When the mean arterial pressure is 100 c.mm. Hg before a meal, as in the above example, the capillary blood-pressure will read 20 c.mm. Hg; and in an hour after the meal, when the arterial pressure rises to 115 c.mm. Hg, or so, the capillary pressure will rise to at least 30 c.mm. Hg. Though this is a large relative rise, the author's observations show that it is not less than this, and that it is often more.

Physical Society, June 12.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Some experiments on shadows in an astigmatic beam of light, by Prof. S. P. **Thompson.** Two years ago Prof. Thompson showed before the Society some experiments on the shadows formed when a thin rod is placed in a beam of light which has passed through a tilted plano-convex lens. In those experiments the peculiar effects were chiefly due to the aberration known as coma. Following up his experiments, Prof. Thompson has investigated the shadows produced when a thin rod is placed in an astigmatic beam.—On a method of determining the viscosity of pitch-like solids, by Prof. F. T. **Trouton** and Mr. E. S. **Andrews.** The various methods which have been proposed for measuring viscosity meet with difficulties when it is attempted to apply them for the measurement of the viscosity of bodies such as pitch. To obviate some of these difficulties a method has been devised in which a constant torque is applied to a cylinder of the substance, and the relative rate of rotation of the ends is observed. From these and the dimensions of the cylinder, the viscosity can be calculated by means of a formula deduced in the paper.—The positive ionisation produced by hot platinum in air at low pressures, by Mr. O. W. **Richardson.** The experiments described in this paper were almost all made at temperatures so low that there was no appreciable negative ionisation. In examining the relation between the current from a positively charged hot platinum wire and the applied E.M.F. at low pressures, results were obtained which indicated that the value of the current fell off with time when the other conditions were kept constant. Further experiments showed that the current died away rapidly at first until it reached a steady value which only disappeared gradually.

Royal Astronomical Society, June 12.—Prof. H. H. Turner, F.R.S., president, in the chair.—The president announced the death of Dr. A. A. Common, and a vote of condolence with his relatives was put from the chair and passed by the meeting.—A letter (accompanying a paper on the present condition of the lunar theory) from Mr. **Nevill,** director of the Natal Observatory, was read, in which the writer stated that the reductions desired by Prof. Newcomb had already been made, and were awaiting publication at the Natal Observatory.—The secretary read a paper, by Prof. E. W. **Brown,** on the verification of the Newtonian law, which gave rise to a discussion in which Prof. Newcomb and others took part.—Mr. **Newall** exhibited and explained a series of slides from spectroheliographs of solar faculæ, &c., taken by a new method by Prof. G. E. Hale at the Yerkes Observatory, and Dr. Lockyer showed slides taken at South Kensington.—Mr. E. W. **Maunder** read a paper by himself and Mr. J. E. Evans on experiments as to the actuality of the "canals" observed on Mars. A drawing of the planet, showing no canals, had been placed before classes of boys at the Greenwich Hospital School, who were set to copy it. It was found that those closest to the original, and therefore able to see the actual detail, drew no canals, but those placed at a further distance made copies in which they delineated canals, in many cases almost exactly as they are represented in drawings by Schiaparelli and others. The author's conclusion was that the so-called "canals" were mainly the interpretation by the observer of faint markings just at the limit of visibility. It also appeared that observers were inclined to prolong into lines any projecting points on the edges of the Martian "seas," and also to draw hard lines at the boundaries of faint shades. Mr. Maunder was convinced that the boys employed in the

experiments were not biased by any knowledge of drawings of Mars showing "canals."—Dr. Johnstone **Stoney** read a paper on an examination of Mr. Whittaker's "undulatory explanation of gravity" from a physical standpoint.—Father **Cortie** read a paper on the spectrum of sun-spots in the region B to D.—Photographs of nebulæ in Auriga, by Dr. Max **Wolf** and Dr. Isaac **Roberts**, were shown on the screen.—A paper by Dr. **Lockyer** on a probable relationship between solar prominences and coronal streamers was taken as read, as well as a paper by Dr. A. W. **Roberts** on the relation between the light changes and orbital elements of close binary systems.—The president briefly noticed a paper by Mr. **Bellamy** on the positions of stars around Nova Geminorum, and also a paper of his own on the possible identity of the Nova with a small star that had been previously photographed by Mr. Parkhurst and Dr. Max Wolf. Prof. Turner concluded that this faint star was not precisely in the place of the Nova.

Zoological Society, May 26.—Mr. G. A. Boulenger, F.R.S., vice-president, in the chair.—Mr. G. A. **Boulenger**, F.R.S., read a paper on the collections of batrachians and reptiles made at Chapadá, Matto Grosso, during the Percy Sladen Expedition to Central Brazil. One species of reptile was described as new to science under the name of *Norops sladeniae*.—A second paper on the collections made at Matto Grosso was contributed by Mr. Edgar A. **Smith**. It contained an account of the shells of the family Bulimulidæ, which was referable to three species.—A communication from Mr. F. F. **Laidlaw** dealt with the collection of acotylean polyclads made by Mr. Cyril Crossland in Zanzibar in 1901–02. Specimens of nine species were contained in the collection, eight of which proved to be new.—Mr. W. **Bateson**, F.R.S., read a paper on the inheritance of colour in fancy rats and mice, in which he gave an account of the work already published relating to the subject, and communicated new observations. The author analysed the evidence at his disposal, showing how far it conformed to Mendel's principles of heredity, and stated the difficulties which were encountered in attempting to apply those principles to certain of the specific results already witnessed. It was hoped that the chief colour-types might be figured in order to promote uniformity of nomenclature.

Geological Society, May 27.—Mr. E. T. Newton, F.R.S., vice-president, in the chair.—An experiment in mountain-building, by the Right Hon. the Lord **Avebury**, P.C., F.R.S. Various observers have endeavoured to throw light on the origin of mountains by compressing pieces of cloth, &c. In these cases, however, the pressure was only in one direction. The author wished to obtain a method of producing compression in two directions at right angles to one another; and, accordingly, he had an apparatus constructed consisting of four beams of wood, which could be approximated by means of screws. In the space, 2 feet across and 9 inches in depth, were placed pieces of carpet-baize and layers of sand, each about 1½ inches deep. The beams were then caused to approach one another until the sand rose in the centre into contact with the glass cover, against which it was flattened out. Casts were made of the surfaces of the different baize-layers, and it was found that in the lower layers the ridges were narrower, shorter, more precipitous, and more broken up than in the higher layers. A second series of casts was exhibited, with the sand and baize having been arranged as before, but with the weight placed on one side. The ridges followed the edges, though not closely, leaving a central hollow. There was a difference between the higher and lower layers, similar to that seen in the first experiment.—The Toarcian of Bredon Hill (Worcestershire), and a comparison with deposits elsewhere, by Mr. S. S. **Buckman**.—Two Toarcian ammonites, by Mr. S. S. **Buckman**. Two ammonites, belonging to the family Hildoceratidæ, found by members of the Cotteswold Naturalists' Field Club, are described and named.

Linnean Society, June 4.—Mr. G. S. Saunders in the chair.—Mr. F. N. **Williams** showed a series of 100 drawings of British Compositæ, 20 being Hieracia, drawn in pen-and-ink by Mr. E. W. Hunnybun, of Huntingdon.—Mr. George **Massee** showed a remarkable felted lining of fungus mycelium of a Polyporus taken from the interior of the node of a bamboo; the specimen belonged to Sir D. Brandis.—Colonel George **Colomb** sent for exhibition a fragment of a branch of a thorn from Hyde Park. This branch shows the mischief done to thorns near London by the larvæ of what had been identified as belonging to the wood leopard moth, *Zeuzera Æsculi*, Linn. The house sparrow was stated to destroy numbers of the perfect insect on their emergence.—Sir Dietrich **Brandis**, K.C.I.E., F.R.S., showed herbarium and museum specimens, from Kew, of *Gelsemium elegans*, Benth., a plant possessing powerfully poisonous properties.—On the anatomy and development of *Comys infelix*, Embleton, a Hymenopterous parasite of *Lecanium hemisphericum*, by Miss Alice L. **Embleton**. The only paper already published on this subject is that by Bugnion on the anatomy, development and habits of an allied fly (*Encyrtus fuscicollis*) parasitic in a caterpillar; there are numerous omissions in the results he records. The present paper also leaves points unexplained, but the author has been able to add some valuable facts to the knowledge upon the subject, the insect on which she has worked being *Comys infelix*, a new species.—Notes on the transition of opposite leaves into the alternate arrangement: a new factor in morphologic observation, by Mr. Percy **Groom**. The author stated that his observations began on *Atriplex rosea*, and to make a graphic representation of results, he plotted the length of the internodes in a given manner, which produced a regular curve; when this principle was applied to Chenopodium and Salsola an entirely different result came out, and a zigzag course was plotted, due to the long and short internodes alternating; at first he suspected this might be due to its nearness to salt water, but inland specimens told the same tale, and neither the influence of day and night nor of salinity could account for it. His belief was that the fusion of branch and stem was the true solution, for axillary branches are given off, but without visible traces of the fusion which does exist; in Salicornia, for instance, the leaves are fused up to the next node above. Observations have been made with a number of other plants as regards the arrangement of leaves and inflorescence.

PARIS.

Academy of Sciences, June 15.—M. Albert Gaudry in the chair.—On the conditions afforded for astronomical observations at the observatory of the Pic du Midi, by MM. B. **Baillaud** and H. **Bourget**. Preliminary experiments with three telescopes showed that this observatory forms an excellent station for astronomical observations.—On the existence of solar radiations capable of traversing metals, wood, &c., by M. R. **Blondlot**. The rays previously discovered by the author in the radiations from an incandescent mantle, and named by him the *n* rays, are now shown to be present in sunlight. Their property of increasing the luminosity of feebly phosphorescent substances was utilised as a means of detection.—On the problem of transformation in Taylor's series, by M. L. **Desaint**.—On the integrals of linear partial differential equations, by M. J. **Le Roux**.—On the barometric formula of Laplace, by M. L. **Maillard**.—On the diurnal period of the *aurora borealis*, by M. Charles **Nordmann**. The intensity of the aurora is regarded as due to two factors, the intensity of the solar Hertzian waves, and the degree of ionisation of the atmosphere. The ionisation being produced by the action of the violet and ultra-violet rays, and recombination occurring during the night, the conclusion is drawn that the diurnal period of the aurora ought to be characterised by a maximum in the early hours of the morning, and this is in agreement with the observed facts.—On the generalisation of a theorem of M. Boucherot, by M. R. **Swyngedauw**.—The wave-length of the *n* rays determined by diffraction, by M. G. **Sagnac**. The refractive index for quartz for the *n* rays, given by M. Blondlot as 2·942, is confirmed; the wave-length in air is about 0·2mm., or about four times the wave-length of the longest infra-red waves discovered by Rubens.—The classification of liquids and crystals from the magnetic point of view, by M. Georges **Meslin**.—The conditions which determine the sense and magnitude of electrification by contact, by M. Jean **Perrin**. The action of H and OH ions is very great in electrical osmosis, so much so that osmosis indicates their presence with a sensibility which

may even surpass that of coloured indicators.—On the prediction of barometric variations, by M. Gabriel **Guilbert.** It has been shown that the velocity of the wind does not always correspond with the barometric gradient. These cases are called abnormal, a normal wind being defined as one which is light for a gradient of 1mm. per geographical degree, moderate for 2mm., strong for 3mm., and violent for 4mm. The study of abnormal winds has led to deductions which may be utilised practically.—On a method of crystallising slightly soluble bodies, by M. A. **de Schulten.** Dilute sulphuric acid, added to a hot dilute solution of barium chloride at the rate of 0·1 mgr. per minute, gave after a month measurable crystals of barium sulphate. Crystals of anglesite and celestine can be obtained similarly, and the method has been successfully applied to the production of several other minerals.—On the substitution of paints having zinc for a basis in the place of lead paints, by M. J. L. **Breton.**—On the so-called colloidal silver, by M. **Hanriot.**—On the fusibilities of mixtures of sulphide of antimony and sulphide of silver, by M. H. **Pelabon.** The fusibility curve of a mixture of the sulphides of antimony and silver can be constructed completely; it presents two maxima corresponding to the existence of two definite combinations, $Sb_2S_3.Ag_2S$ and $Sb_2S_3.3Ag_2S$. It shows besides three minima corresponding to three different eutectic mixtures.—On the etherification of sulphuric acid, by M. A. **Villiers.** The limits observed in the case of some mixtures of alcohol with sulphuric acid of different strengths after standing twenty-five years at the ordinary temperature are practically identical with those attained by the same mixtures after 221 days at 44° C., or 154 hours at 100° C.—On some derivatives of aminopyromucic acid and furfuranamine, by M. R. **Marquis.**—The action of phosphorus trichloride upon glycerol, by M. P. **Carré.** PCl_3 acts upon glycerol in the same manner as with glycol. The compounds $P_2O_6(C_3H_5)_2$ and $P(OH).O_2C_3H_5Cl$ are immediately decomposed by water, giving $P_2(OH)_4.O_2.C_3H_5.OH$ and $P(OH)_2.O.C_3H_5(OH)Cl$, the calcium salts of which were isolated.—The action of hydrogen sulphide upon methyl-ethyl-ketone, by M. F. **Leteur.** The compound $(C_4H_8S)_3$ has been isolated, which can be regarded as a polymer of an unknown butanethione.—On two new hydrocarbons isomeric with campholene and camphene, by MM. L. **Bouveault** and G. **Blanc.**—The synthesis of 2:2-dimethylglutaric acid, by M. E. E. **Blaise.**—On formic acid from the air, by M. H. **Henriet.** In a previous note the author has indicated the existence in the air of a nitrogen compound with an acid which appeared to be formic acid. The substance has now been isolated in larger quantity, and the identity of the acid with formic acid completely proved.—The distribution of some organic substances in the geranium, by MM. E. **Charabot** and G. **Laloue.** The terpene compounds of the geranium are almost entirely localised in the leaves.—Observations on phenylglycollic acid, by M. Œchsner **de Coninck.**—The action of iodine bromide on albumenoid materials and on the organic nitrogen bases, by M. A. **Mouneyrat.** Iodine bromide forms addition compounds with many substances containing nitrogen, and is not necessarily a test for the existence of the pyridine ring in the molecule.—On the presence of indoxyl in urines, by M. L. **Maillard.** A reply to a note on the same subject by M. J. Gnezda.—On some peculiarities observed in the renal tubes of *Barbus fluviatilis*, by M. J. **Audigé.**—On a criterion of irreducibility in statistical data, by MM. Charles **Henry** and Louis **Bastien.**—New expression of the law of electrical stimulation, by M. and Mme. L. **Lapicque.** The formula given by Weiss, $vt=a+bt$, where v is the voltage, t the time, and a and b constants, is found to be only roughly approximate; the experiments of the author require a term with an additional constant to be added to the formula of Weiss.—On some nuclear phenomena of secretion, by M. L. **Launoy.**—Cerebral inertia relating to the reading of printed letters, by MM. André **Broca** and D. **Sulzer.**—Observations on the treatment employed for the destruction of Pyralis of the vine, by M. Joseph **Perraud.**—New researches on the epiplasm of the Ascomycetes, by M. A. **Guilliermond.**—Researches on the nutrition of the tissues in galls, by M. C. **Houard.**—On the cave of Font-de-Gaume, and on the age of the cavern, by M. E. A. **Martel.**—On a living safety lamp, by M. Raphael **Dubois.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 25.

UNIVERSITY COLLEGE MATHEMATICAL SOCIETY, at 5.30.—Some Present Aims and Prospects of Mathematical Research: E. T. Whittaker.

FRIDAY, JUNE 26

PHYSICAL SOCIETY, at 5. (University of London, South Kensington).—(1) Electrical Effects of Light upon Green Leaves; (2) Blaze-Currents, (*a*) of a Vegetable Tissue, (*b*) of an Animal Tissue; (3) Quantitative Estimation of Chloroform Vapour in Air by (*a*) Oil Absorption, (*b*) Densimetry: Dr. Waller.—The Temperature Limits of Nerve-Action in Cold-blooded and in Warm-blooded Animals: Dr. Alcock.—(1) On the Movement of Unionised Bodies in Solution in an Electric Field; (2) On the Passage of Nervous Impulses through the Central Nervous System: Dr. Hardy.

TUESDAY, JUNE 30.

SOCIETY FOR THE PROMOTION OF HELLENIC STUDIES, at 5.—Annual Meeting.

FARADAY SOCIETY (Rooms of the Chemical Society, Burlington House), at 8.—The Present Position of the Theory of Electrolysis: W. C. Dampier Whetham, F R S.—Chlorine Smelting, with Electrolysis: J. Swinburne.—Total and Free Energy of the Lead Accumulator: Dr. R. A. Lehfeldt.—Electrolytic Apparatus: Dr. F. Mollwo Perkin.

THURSDAY, JULY 2.

INSTITUTION OF MINING ENGINEERS, at 11 a.m.—Luxemburg and its Iron-ore Deposits: J. Walter Pearse.—The Lake Superior Iron-ore Region: Prof. Van Hise.—Mineral Resources of the State of Rio Grande do Sul, Brazil: H. Kilburn Scott.—Electric Coal-cutting: W. E. Walker.—Pneumatic and Electric Locomotives in and about Coal-mines: A. S. E. Ackermann.—Electrical Plant Failures, their Origin and Prevention: A. C. Cormack.—The Electrical Driving of Winding-gears: F. Hird.—Electric-power Distribution by Continuous Current for Mining and General Purposes in North Wales: T. P. Osborne Yale.

RÖNTGEN SOCIETY, at 8.30.—Annual General Meeting.

FRIDAY, JULY 3.

INSTITUTION OF MINING ENGINEERS, at 11.30 a.m.—Further Remarks on the Portuguese Manica Gold-field: A. R. Sawyer.—Coal-fields of the Faröe Islands: E. A. Greener.—Miners' Anæmia or Ankylostomiasis: Dr. J. S. Haldane.—Water-softening Plant: Vincent Corbett.—The Redevelopment of the Slate-trade in Ireland: O. H. Kinahan.—The Smelters of British Columbia: W. Denham Verschoyle.—The Common-sense Doctrine of Furnace-draught: H. W. Halbaum.—The Ventilation of Deep Mines: Arthur C. Murray.

THE BIOGRAPHY OF HELMHOLTZ.

Hermann von Helmholtz. By Leo Koenigsberger. In three volumes. Vol. i. Pp xi+375. Price 8 marks. Vol. ii. Pp. xiv+383. Price 10 marks. Vol. iii. Pp. xi+142. Price 3 marks. (Brunswick: Vieweg, 1903.)

I.

Education and Physiological Work.

THE third and last volume of Koenigsberger's biography of the great natural philosopher has now appeared. The whole work is worthy of its subject; the author made it his aim, as he tells us in his preface, to set forth Helmholtz's manifold and various achievements as a discoverer in such a way as to render them intelligible to all scientific readers. Helmholtz is best known by his discoveries in experimental physics, but during the first half dozen years after the completion of his professional education, the business of his life was that of an army surgeon. It was as an army surgeon that he published, between 1842 and 1848, those remarkable researches on fermentation, on the nature of muscular contraction, and on the production of heat therein, the results of which served as the foundation for the building up of a new science of physiology. Even the treatise on the "Erhaltung der Kraft," or, as we now call it, the conservation of energy, although mainly physical, exercised its chief influence on physiologists. In natural philosophy the principle set forth in it had been already recognised, but had not as yet been presented to the physiological student as a fundamental doctrine, or successfully applied to the phenomena of life.

The biography of a man of great intellectual pre-eminence fulfils its highest purpose by enabling us to form a just estimate of the antecedent and surrounding influences which made him what he was. Herr Koenigsberger has treated his subject in such a way as to afford the information that the scientific reader seeks. How can we account for the production of a man of such extraordinary endowments? Did Helmholtz owe his intellectual superiority to his innate qualities, to his parentage, to his education, and if to the latter, was it due to his teachers or to his contemporaries? Koenigsberger's indications lead us to believe that in each of these respects his life was influenced by circumstances exceptionally favourable to his intellectual development.

Nationally, Helmholtz was of mixed descent. It may be assumed that his father was German, but his mother was half English, half French. Her maiden name, Caroline Penn, was derived from the great Quaker of the seventeenth century, who himself was the son of an almost equally distinguished English admiral. On the female side she was of Huguenot descent.

There can, I think, be no doubt that the moral and intellectual atmosphere of the Helmholtz home was excellent. The little that we are told of his mother indicates that she was a woman of great simplicity of character, but at the same time of unusual intelligence, who devoted herself heart and soul to promoting the happiness of her husband and children. His father was at the head of the Gymnasium at Potsdam, a position which he had attained after many years of arduous struggle with adverse circumstances. He appears to have been an enthusiastic teacher, who made it his aim rather to evoke in his pupils a love for the classical writers than to drill them in grammatical niceties.

Of Helmholtz's childhood we are told that, although his mother recognised in her firstborn "Geist und Verstand," there was no other indication of infantile precocity. At nine he entered the lowest class in the Gymnasium, but in a year was half-way up the school. His progress, however, was retarded by the difficulty which he had in learning anything by heart. During his first three years he went through the regular classical work of the school, but he appears even at this early age (ten to thirteen) to have done much extra work under his father's direction, who encouraged him to extend his studies beyond the limits of the school course. At thirteen he began the study of mathematics under a teacher who appears to have had as great a faculty for exciting enthusiasm for work in natural science as the father had in literature. Helmholtz continued his classical work, but became more and more engrossed by his studies in mathematics and physics, the subjects which, he says in his "*Abiturientenvita,*" "omnium disciplinarum maxime a pueritiâ me delectavit," so much so that when the rest were engaged in construing, he "beguiled the tedious hour" by working problems "under the table." By the time he was fifteen, he had already made up his mind to devote his life to natural science.

His father's means were so limited that the only way in which this desire could be gratified was by taking the study of medicine "into the bargain." He therefore at sixteen, while still a "gymnasiast," became a pupil in the Friedrich-Wilhelm-Institut at Berlin (the Pépinière) for the training of army medical officers. Two years later (at eighteen) he passed the *Abiturienten-Examen*, showing "comprehensive and thorough knowledge in the elements of mathematics and physics." He obtained at the same time distinction in classics, exhibited a good knowledge of French, English, and Italian, and had made sufficient progress in Hebrew to be able to offer that language as an extra subject. It was thus that he was equipped for the business of his life. That he possessed extraordinary natural endowments cannot be questioned, but it is no less certain that he owed the early maturity of his intellect and his exceptional heuristic power to an almost perfect education.

Whatever be the place among contemporary physicists to which his achievements entitled him, it can scarcely be questioned that as a physiologist he was *primus inter pares*. He was the first to understand what is meant by the well-known definition of life as "organism in action," and thus to distinguish clearly between that branch of the science of life which deals with organism and that which relates to the chemical and physical processes by which its action manifests itself. In the former Helmholtz did not much interest himself, and consequently was not, in the modern sense of the word, a biologist. His aim

was not to inquire *why* the animal (or plant) body assumes in its development the characters which it presents to the naturalist, but rather to discover in what processes vital action consists, and to prove that these processes are identical with those of inorganic nature, and can only be investigated by the methods of exact science. But Helmholtz was far from supposing that these methods could be applied either to organism and its evolution or to the study of mental processes, and expressed his distrust of the efforts made by others in this direction, with perhaps too great contempt.

Helmholtz's professional education began when he left school in 1838, and occupied four years. It is noteworthy that, notwithstanding the almost incredible amount of work which was imposed on the students of the Pépinière by a curriculum which not only included anatomy, physiology, pathology, and practice, and the sciences then regarded as ancillary to medicine, but also logic and metaphysics, ancient history, and modern languages, Helmholtz still found leisure for other pursuits. He was not only able to obtain that mastery of music of which he was afterwards to make so splendid a use, but also to pursue without any assistance, except such as he derived from books, the higher branches of mathematics, in the elements of which his schoolmaster (Meyer) had so thoroughly grounded him.

It need scarcely be said that during this period of ceaseless exertion he became intimate with the greatest of his teachers, J. Müller, and thus, as he said himself, had another opportunity of observing "wie die Gedanke selbstständiger Köpfe sich bewegen." This intimacy was, no doubt, of great value to him, but there is no sufficient ground for the conjecture which has often been made that it was from Müller that he derived his inspiration. The two men were cast in such different moulds that this was scarcely possible. The subject which Helmholtz selected for his Latin graduation essay ("The Structure of the Nervous System in Invertebrates") was no doubt suggested by Müller, but Helmholtz was no sooner himself free ("selbstständig") than he followed his own bent. It seems probable that, even when he was working assiduously with Müller as a biologist, he anticipated the direction in which his future studies would lead him, and was already aware that physics and chemistry, not biology, would afford him effectual methods of research.

Helmholtz graduated in 1842, and soon entered on his duties as a military surgeon. These happily gave him sufficient leisure for his scientific work. His first research, of which the results were published in Wagner's "Handwörterbuch," was on the relation between the work done and the heat produced in muscular contraction. It was important as setting forth one of the fundamental facts on which the new science was to be built, and as preliminary to the treatise on the "Erhaltung der Kraft," which appeared two years later. Of the genesis of this work Koenigsberger gives an interesting account. The introduction to it was written in 1846, the very same year in which, at the age of twenty-five, he passed his final *Staatsexamen* as a practitioner of medicine and surgery, his examiners possibly little guessing whom they had before them. The manuscript of the introduction was put for friendly criticism into the hands of du Bois-Reymond, who, however, would make no change in it, regarding it as an "historisches Document für alle Zeiten." It was forthwith communicated to the recently founded Physical Society of Berlin, the young and active members of which thus became acquainted with the law of the conservation of energy long before it had been discussed by academicians. By the Physical Society it was received with enthusiasm, but when offered to Poggendorff for publication in the *Annalen*, he declined it as being too theoretical, promising, however, to accept it as soon as experimental proofs were forthcoming.

The four years during which Helmholtz was charged with regimental duties were so productive that, in 1849, when a vacancy occurred in the University of Koenigsberg, he was selected by the Minister of Public Instruction among the four whom J. Müller had recommended, namely, Ludwig, Helmholtz, du Bois-Reymond, and Brücke, as the men most capable of advancing science in the "physico-physiological direction." All of these men, whose claims Müller estimated to be equal, were young, but Ludwig was the senior, and would have received the appointment had not a suspicion of radicalism, wholly unfounded, attached to him. So Helmholtz became, at twenty-eight, professor of physiology with the magnificent salary of 120*l.* a year!

Helmholtz's removal to Koenigsberg was followed by a period of astonishing fruitfulness in discovery. The first new subject to which he directed his attention was that of the measurement for physiological purposes of extremely short intervals of time, and the application of these methods to the determination of the rate of transmission in nerve. This he accomplished with such completeness and exactitude that his results can, even now, be accepted without question. In the meantime he continued those studies in physiological optics which led to the discovery of the ophthalmoscope. This, as well as the subsequent discovery of the mechanism of accommodation of the eye for distance, was communicated to the Physical Society. Then followed an investigation of the time-relations of induction currents, a research of great importance in the technique of experimental physiology. His first researches on colour-vision were published in Poggendorff's *Annalen* in 1852, in which journal also appeared, about the same time, another research of great value in its bearing on electro-physiological questions—an investigation of the "distribution of currents in bodily conductors."[1] It was towards the end of the Koenigsberg time that Helmholtz made his first visit to England. In his letters home he refers with evident pleasure to his intercourse with English physicists, and especially to the impression made upon him by Faraday's "herzgewinnendes Wesen," and observed with great interest how "old bits of wood and wire" sufficed him for the

[1] See vol. i. p. 177.

making of the greatest discoveries. He no less highly appreciated the friendly welcome given him by the Astronomer Royal, Airy, and the opportunity of exploring Greenwich Observatory, and of seeing in operation the first successful method of recording photographically the readings of magnetic and meteorological instruments. With Thomson, Helmholtz did not come into personal relation until August, 1855, when they met at Kreuznach. Helmholtz describes (in a letter to his wife) his astonishment when a man whom he knew as one of the first of living mathematical physicists appeared to him as a "Jüngling von ganz mädchenhaften Aussehen," but possessed of a degree of acuteness, clearness, and versatility which he had never before met with. It can well be imagined how these two young discoverers must have enjoyed and profited by the exchange of thought on fundamental questions which each of them had done so much to elucidate.

The same year Helmholtz accepted the chair of anatomy and physiology at Bonn, his motive for doing so being that his wife, whose health was precarious, might have the advantage of a milder climate. At that time the two subjects were still united, so that Helmholtz was obliged to resume the teaching of descriptive anatomy. This drawback was, however, of short duration, for two years later he was invited to Heidelberg, where the conditions were much more favourable. Notwithstanding the onerous nature of Helmholtz's professional engagements, the fifteen years of his residence at Bonn and Heidelberg were almost as productive as those which had preceded them. It was at Bonn that he sent to the press the first part of his famous treatise on physiological optics, which was not completed until 1895, and there also that he carried out many of the researches on musical sounds which were embodied in his treatise on "Sensations of Tone." At Bonn, too, he published his first mathematical paper "On the Movement of Fluids" (1858), which led on to his experimental researches at Heidelberg in 1860. During the whole period it appears that he published some forty-six papers of importance, of which thirty-seven, including those on optics and acoustics, were on physiological subjects, the remainder being physico-mathematical.

After his appointment to the chair of physics at Berlin, his only physiological publication was the essay entitled "Thought in Medicine," in which he illustrated in the most striking way the application of the scientific method to pathological questions. (The chapters of Koenigsberger's work which relate to Helmholtz as a mathematician will be treated by abler hands. Many readers who may not have leisure to look into this admirable biography would have been glad had it been possible to give some account of Helmholtz's views as to the limits of a scientific inquiry and the relation between the experimental sciences and philosophy. Want of space forbids this.)

In Koenigsberger's book the reader will find ample material for the decision of the question which presented itself at the outset, that of the conditions which led to the development of so splendid a character. To the present writer it seems evident that Helmholtz's personal qualities—his sagacity, modesty, truthfulness, and astonishing power of work—could be in great measure attributed to home and school influences, and that his success as an investigator was due in part to his having entered on his career as a physiologist at a time when the progress of the exact sciences had rendered their methods applicable to the investigation of vital phenomena, and in part to his singular good fortune in having as his fellow-students such men as du Bois-Reymond, Ludwig, and Brücke, each of whom was as enthusiastic as himself, and scarcely inferior to him in intellectual endowments.

J. BURDON-SANDERSON.

II.

PHYSICO-MATHEMATICAL RESEARCHES.

Herr Koenigsberger gives us an account of Helmholtz which is extremely interesting, and not unworthy of the investigator of whom he writes. Though he paints for us a fascinating picture of Helmholtz as a man, it is with work as a great physiologist and physicist that he chiefly deals.

A review of that part of the biography which deals with the education and physiological work of Helmholtz precedes this notice, which is confined to a brief account of that part of the book treating of his physico-mathematical writings. Helmholtz's first mathematical paper was "On the Integrals of Hydrodynamical Equations which correspond to Vortex Movements," and was published in 1858, during his short stay in Bonn as professor of anatomy and physiology. In the following year, after his migration to Heidelberg as professor of physiology, appeared his paper "On the Motion of Air in Pipes with Open Ends." These two papers contain some of his most brilliant mathematical deductions, and are characterised by their freedom from the artificial or inaccurate assumptions of his predecessors. Further work in this direction was for the time prevented by family troubles. In June, 1859, his father died of a sudden stroke, and Helmholtz, worn out with sorrow at his loss, with anxiety for his wife, and with his own bad health, was obliged to turn to work requiring less concentration of thought. At the end of the year his wife died. For some time his health remained in an unsatisfactory state, and he was subject to headache and fainting fits. However, he forced himself to work, "which alone could give him power to hold out," and continued his hydrodynamical investigations, publishing in April, 1860, his paper "On the Friction of Viscous Fluids." His experimental researches on sound then led him to study the mathematical theory of violin strings and reed organ pipes.

Continuing his researches in acoustics and optics, he was led by the consideration of the wave motion near the end of an open cylindrical tube to investigate the distribution of electricity near the circular intersection of two surfaces. However, in this, the first of his many papers on mathematical electricity, he had been anticipated by Thomson. He then for some years confined himself mainly to physiological work, and it was not until 1868 that he was again led by his

acoustical researches to the study of hydrodynamics. Shortly after this his physiological work induced him to again attack electrical problems. From the study of electrical oscillations he proceeded to a discussion of the most general form of expression for the potential of single "Stromelemente," and of the differential equations which determine the motion of electricity. In this first treatise on electrodynamics, Helmholtz aimed at giving a clear summary of all results previously obtained.

In 1871 Helmholtz was appointed to the professorship of physics at Berlin in succession to Magnus, which post he held until 1888. From this time onward he confined himself almost entirely to physics, and did very little more physiological work. In the following year, after the marriage of his daughter Käthe, and a visit to Scotland (where he met Tait, Andrews, Huxley, Brown, Sylvester, &c., and found golf less easy to master than science), he published further papers "On the Theories of Electrodynamics." In these he replied effectively to the criticisms of Bertrand, Weber, &c., and, basing his researches on Neumann's potential law, he investigated the various theories that had been put forward, showing that Faraday's assumption of dielectric polarity was the only theory consistent with observed properties of open and closed circuits. For a short time after this he applied his versatile genius to the problem of artificial flight and guidable balloons, made valuable contributions to the theory of the microscope and anomalous dispersion, and turned his attention to the origin of thunderstorms. He then returned for some years to his researches in electricity, and applied Faraday's theories to electrochemistry, producing papers on electric currents in fluids and "elektrische Grenzschichten."

In 1878 commenced his lifelong friendship with Hertz, whose investigations led Helmholtz back to his electrodynamical researches, and to the discussion of the electromagnetic theory of light. In 1881 he again visited England, where he delivered his famous "Faraday lecture" (one of the best lectures he ever gave), which was received with the greatest enthusiasm. The delivery of this discourse led him to further investigations in electrochemistry, and in "The Thermodynamics of Chemical Processes," published in 1883, he discusses the relations of chemical combination, heat, and electrical potential, distinguishing between the "free" energy of a system which can be entirely converted into work and the "bound" energy which cannot be so converted. After journeys to Rome and England, he undertook a masterly development of the principle of least action, a principle which he considered as probably being the controlling law of all reversible processes of nature.

During the last year of his professorship at Berlin Helmholtz returned to his work on electrical and thermodynamical chemistry, and to the development of the "principle of the decrease of free energy in chemical processes." In 1888 he was appointed president of the newly-founded Physico-technical Institute, a position in which he had comparative freedom from routine work, and so was enabled still more thoroughly to devote himself to those investigations for which he was so peculiarly fitted. His first great work in his new position was the adaptation of the equations of hydrodynamics to the case of layers of gases of varying density, and the application of his results to meteorological phenomena. The remaining four years of his life were devoted to more work on the mathematical theory of electricity. The most important papers were those on the application of the principle of least action to Maxwell's electrodynamical equations, on the electromagnetic theory of colour dispersion, and on Maxwell's theory of the motion of the ether. He died, after two months' illness, in 1894.

HAROLD HILTON.

THE EARTH-HISTORY OF CENTRAL EUROPE.

Central Europe. By Prof. Joseph Partsch, Ph.D. Pp. xiv+358; with maps and diagrams. (London: William Heinemann, 1903.)

PROF. PARTSCH'S geography of Central Europe forms a volume of the series "Regions of the World," edited by Mr. H. J. Mackinder. Written in German, it has been well translated by Miss Clementina Black, and has also undergone a little condensation, probably to its advantage. On the east and part of the south, the region has fairly definite physical boundaries, in other directions they are more often political; but practically Central Europe includes the two great empires of Germany and Austro-Hungary, with Switzerland, Belgium and the Netherlands on the one hand, Montenegro, Servia, Bulgaria and Roumania on the other. But in the main there is a general correspondence between the political and the physical boundaries of the region, for Central Europe, geographically speaking, as Prof. Partsch remarks, is a three-fold belt of Alps, of inferior chains and of northern lowlands, and wherever one of these elements dies out Central Europe comes to an end. This is the best natural definition, though we should have preferred the term central highlands to "inferior chains," and a little clearer insistence on the fact that the great mountain chains of Europe—the Alps, Pyrenees and Carpathians—are comparatively modern physical upstarts, the highlands being much more ancient regions, which, like some old families, have come down in the world. Still, Prof. Partsch makes it clear, in a chapter which certainly would not stand any more compression, that the development of Central Europe was a long and complicated story. His remarks on traces in the Alps of valley systems older than the present, illustrated by some rough but sufficient diagrams after Prof. Heim, will be very suggestive to students, though full justice can hardly be done to the subject within the limits of this volume, because mountain making in this region was a complicated and intricate process, involving many speculative elements. He does well also in calling attention to the aggressive habit of some rivers; the more active one cutting back through the old water parting and capturing the other's tributaries. The Maloya Pass affords, of course, a typical example of

this process, but it has probably occurred on an even greater scale under the shadow of Monte Rosa, where the depths of the Upper Val Anzasca have replaced summits which once connected the former peak with the ranges about the head of the Saaser Visp.

But before Alps, Pyrenees, or Carpathians existed, Europe had its river systems, which, notwithstanding their revolutionary effects, may still be traced. For these we must look to the great zone of the central highlands, which, in earlier days, must have marked the watershed of Europe so far as it then existed. We can, indeed, infer this history from Dr. Partsch's chapters, but its geographical outlines might well have been drawn with a firmer pencil. But his sketches of the different regions of Europe are clear and graphic, not forgetting the scenery and structure of the great Alpine chain, among which we may mention that of the Karsh region of the south-east, with its singular system of underground drainage, outliers of which may be found here and there farther west, notably in the Steinerne Meer, near the König See, and sometimes even in the Western Oberland. The chapters on the North German lowland and adjacent seas, on climate, ethnology, and economic geography are particularly good, and the value of the last is increased by small maps showing the chief productive areas of cereals, potatoes, vines, and other useful plants, as well as of minerals. The growth and relations also of the States into which Central Europe is now divided are briefly sketched, and the professor, in remarks upon the zeal lately shown by Switzerland in fortifying the heart of the Alps, takes some little pains to assure this State that the Teutonic Codlin, not the Gallic Short, is the friend. Who lives, will see.

We think Prof. Partsch makes "block" mountains and fractures a little too prominent, and object to his use of the term rift valley, though aware that he can quote precedents. If the Upper Rhine is a rift valley, we are unable to see how it differs from a "fault valley," *i.e.* one the general line of which has been determined by a fault or set of faults. Rift valley, in the most proper sense of that epithet, belongs to an extinct phase of geology, when the Alpine lakes were located in gaping fractures; it becomes almost absurd, as Prof. Partsch's own diagram shows, when applied to the above-named region or to the valley of the Jordan, but there are now geologists who take much pleasure, first in coining a dubiously appropriate term and then misapplying it with a lavish hand. One or two other dubious matters may as well be mentioned. It would be more correct to say that the crystalline rocks of the Mont Blanc *massif*, on their underground course towards the Bernese Oberland, plunge under the Alps of Vaud than of Fribourg; it is misleading to speak of schistose rocks being associated with the *nagelfluh*, and it would have been well to have spoken more dubiously about ancient coral reefs as origins of the East Alpine Dolomites. These, however, are but details. The book displays a temperate avoidance of extreme views, is well printed and illustrated, is clearly and attractively written, and will be most useful to both teachers and learners.

T. G. B.

OUR BOOK SHELF.

A Treatise on the Theory of Solution, including the Phenomena of Electrolysis. By W. C. D. Whetham. Pp. x+488. (Cambridge: University Press, 1902.) Price 10s. net.

THE present work is a rewritten and greatly expanded version of the author's book on "Solution and Electrolysis," published in 1895. It embraces practically all the material on the subject of solutions which is dealt with in the ordinary text-books of physical chemistry, except that part concerned with velocity of reaction and purely chemical equilibrium. The treatment throughout is characterised by great clearness, especially in the physical and mathematical portions, so that the volume may be warmly recommended to students of chemistry who desire to increase their knowledge of this department of the subject. The first chapter is on the general principles of thermodynamics, so far as they are necessary for subsequent developments, and is followed by chapters on the phase-rule and on solubility. Then comes the discussion of the phenomena of osmotic pressure, and the related magnitudes of the lowering of vapour pressure and of the freezing point, to be succeeded by a judicious chapter on the theory of solutions in which the hypotheses of molecular bombardment and of chemical combination are weighed and compared. Thereafter come four chapters on electrolytic conductivity and electromotive force, leading to an exposition of the theory of electrolytic dissociation. Two useful chapters on diffusion in solution, and on solutions of colloids, conclude the work.

A valuable appendix consists in the tables of electrochemical data compiled by the Rev. T. C. Fitzpatrick, and reprinted from the British Association Report of 1893. This extends to nearly 80 pages, and gives the conductivity, migration, and fluidity data which had at that time been determined for aqueous solutions. The book is also provided with an excellent index, which adds to its value as a work of reference.

The Study of Mental Science. By Prof. J. Brough. Pp. 129. (London: Longmans, Green, and Co., 1903.) Price 2s. net.

THIS very readable little book is a collection of five lectures in which Prof. Brough has urged with force and eloquence the claims of logic and psychology to take their place in every curriculum designed to give a liberal education. He claims that the study of logic develops and brings clearly before the consciousness of the student the "natural sense of method" which in the scientific specialist too often works in devious subterranean fashion. Logic, treated as a study of scientific method, should be taught at that stage in the educational course at which a general survey of knowledge has been made, and before the student enters upon one of the more specialised courses of study prescribed by the honours schools of our universities. This sound principle, practically interpreted, means that logic should be made an obligatory subject for all candidates in the matriculation examinations of the universities, that, for example, in the "Little-go" logic should replace "Paley," which for the intelligent student is merely a study in one branch of logic, the study of fallacies. For psychology our author does not attempt to claim so urgent and universal importance. It is rather as a complement to the "humanities" that he urges its claims. In the modern world "the panorama of spiritual presentation through which we move" grows overwhelmingly rich and varied, and the mind can hope to cope with it profitably only when its knowledge of spiritual fact is systematised by analysis of psychical processes and by clear conceptions of the elements so revealed and of the laws of their conjunction. Prof. Brough is known as an enthusiast

for the modern experimental treatment of psychology, and has the merit of having introduced these methods in the University of Wales; it is therefore regrettable that he has not dwelt upon the value of psychology, so treated, as a training in accurate observation. For no other experimental science exercises so constantly, or makes so exacting demands of, the faculty of close observation and the power of voluntary control of the attention, the development of which two powers is, or should be, a prime object of all educational efforts.

W. McD.

Photography. Edited by Paul N. Hasluck. Pp. 160. (London, Paris, New York, and Melbourne: Cassell and Co., Ltd., 1903.) Price 1s.

Hand Camera Photography. By Walter Kilbey. Pp. 124. (London: Dawbarn and Ward, Ltd., 1903.) Price 1s. net; cloth, 2s. net.

THESE little books are both intended for beginners in photography. The comprehensive title of the first is reflected in the claim made in the preface that the "Handbook contains, in a form convenient for every-day use, a comprehensive digest of the knowledge of photography, scattered over more than twenty thousand columns of *Work.*" Doubtless the volume will be of value to readers of *Work* in saving many a reference to its thousands of columns, and as it is written chiefly by a professional photographer, others will probably be interested in such chapters as that on retouching. Much of the matter is too concise. It is impossible, for example, to give useful directions for the making of a 20 × 15 wet collodion negative in less than one small page, including instructions as to what to buy for the purpose.

The second volume is of a different kind. It is written by an amateur for amateurs, and the author has proved by his published photographs that his experiences are valuable. Of course, everyone will not corroborate all the opinions expressed, for the book has individuality and does not pretend to be a comprehensive treatise. It is essentially popular in style, and meets several difficulties that trouble beginners, and that many authors do not think of referring to. But Mr. Kilbey has surely forgotten himself when he suggests the use of a swing back in order to get such a view as an abbey with a foreground of rushes more easily into focus. Some ten pages further on an example of distortion due to tilting the camera is illustrated. We fear that some will infer from these illustrations that tilting the camera gives distortion, while swinging the plate does not. The book will be found to be a very useful guide by those who use hand cameras, and whose knowledge of photography is but slight, while others who may rank with the author in experience can hardly fail to find useful suggestions.

Mise en Valeur des Gîtes Minéraux. By F. Colomer. Pp. 184. (Paris: Gauthier-Villars, 1903.) Price 3 francs.

MOST of the French treatises on mining hitherto published deal chiefly with the extraction of coal, and this unpretentious and inexpensive volume will therefore undoubtedly prove useful to managers of metalliferous mines. It gives a clear summary of modern practice in metal mining. It is up-to-date and compact with facts. The matter is divided into ten chapters, dealing respectively with the definition of an ore-deposit, access to the deposit, method of working, breaking ground, rock-drills, explosives, transport, raising ore, drainage and ventilation. The work concludes with a brief glossary of technical terms. The absence of illustrations renders some of the descriptions somewhat obscure. The author has, however, carried out his task with care and accuracy, and has produced a volume valuable to the student desirous of becoming familiar with French mining terms.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Psychophysical Interaction.

MY authority for attributing to Descartes the distinction between "creation" and "direction" is Leibniz's "Theodicée" (Erd. 519). I ought to have stated more clearly than I did that he, of course, conceived of the problem in the form in which it presented itself to his age as one of "motion" rather than of energy and momentum. In referring to the history of the discussion at all, I merely meant to indicate its antiquity. This, of course, is no reason why it should not be reopened now. Every generation of thinkers has to adjust old solutions to new forms of a problem. It is, however, a reason why we should inquire whether a controversy of so long a standing may not be founded on a radical misunderstanding.

The object of my letter, if I may repeat it, was not to advocate the removal of the discussion from the field of fact to the *nirvana* of monistic idealism, as Sir Oliver Lodge suggests, but the preparation of the way for a better understanding between the combatants by inviting them, experimentally, at least, to consider the facts from a different point of view, or rather from the point of view of the most fundamental of all facts, our own will and personality. In making this suggestion, I expressly disavowed the introduction of anything transcendental that might dazzle the eyes or divert attention from the "landscape" or the "wayside." The suggestion, on the contrary, was that wayside facts might be better understood and unsatisfying controversy avoided, while, at the same time, the end which I understand Sir Oliver Lodge desires in the vindication of the reality of mind might be more legitimately achieved if we reminded ourselves at times that the road is a part of the landscape, and that both of them (to recall an old simile), both as they are and as they are known, are the work of the sun. So far from being put forward in the name of any one philosophy, this point of view, I maintained, is one which psychologists, pluralists and monists, realists and idealists alike, show a growing tendency to adopt.

The point at which the difference of attitude I advocate is most likely to come home to the physicist is that which Sir Oliver Lodge himself rightly emphasises in the donkey and carrots illustration. The psychologist only asks him to carry this far enough, following the facts as they take him from animal reaction to conscious volition and determination by ideas, on the chance that, when this point has been reached, a new view of the relation of the terms he has been accustomed to oppose to each other as matter and mind may be seen to be possible, and questions such as that raised by Mr. Culverwell in the letter following Sir Oliver's own in your issue of June 18 as to whether one state of motion in the molecules of the brain could in theory be deduced from the preceding state, of whatever interest to the physicist, to be irrelevant to the more ultimate question of the reality and efficiency of mind. If the conception of a physical world as opposed to a mental can be shown (as psychologists are agreed it can) to be one which has grown up within the conscious subject as a mode of organising and utilising his experience, what reason can there be for representing matter as an independent reality reacting upon another which we call mind?

In conclusion, may I say that it seems to me one of the misfortunes of present day specialism that physicists and psychologists, like mind and matter themselves, on the common view (though unfortunately without their pre-established harmony), move in different spheres, writing in different journals, and exchanging words, if at all, from a distance? I am grateful to NATURE for its hospitality on the present occasion, and to Sir Oliver for his note of welcome. May I express the hope that he will return the visit and continue the discussion in the pages of *Mind*? I think I may promise him an equally hearty welcome, and if I am right as to present-day tendencies in psychological science, a congenial atmosphere. J. H. MUIRHEAD.

Birmingham, June 21.

Tables of Four-figure Logarithms.

FOR many scientific computations it is sufficiently accurate to work to four figures, but there have been complaints that the usual tables of four-figure logarithms are not accurate in the fourth figure. Thus, log 1·019 is given as 0·0080, whereas it ought to be 0·0082. The errors are met with only in numbers from 1000 to 2000. In consequence of this, some such tables are accompanied by a table specially intended for numbers between 1000 and 2000. Many physicists and chemists refuse to use four-figure tables for this reason, and advocate the use of five-figure tables, in spite of their greater size and the waste of time.

I beg to point out that Mr. J. Harrison has got over the difficulty in a very simple manner in the four-figure table published by him recently in his book, "Practical Plane and Solid Geometry." Even he, however, cannot avoid a possible error of 1 in the last figure. The first ten rows of differences have been replaced by twenty. The rest of the table is unaltered. I give a specimen of an old row of figures and how it is replaced. The cause of inaccuracy in the old system is apparent at once.

	0	1	2	3	4	5	6	7	8	9	1	2	3	4	5	6	7	8	9
11	0414	0453	0492	0531	0569	0607	0645	0682	0719	0755	4	8	11	15	19	23	26	30	34
							This is replaced by												
11	0414	0453	0492	0531	0569						4	8	12	15	19	23	27	31	35
						0607	0645	0682	0719	0755	4	7	11	15	19	22	26	30	33

It is to be hoped that all four-figure logarithm tables will in future be printed in this way. The Board of Education is now printing tables of this kind for use in evening science classes.

JOHN PERRY.

Ship's Magnetism.

IN a review of my book on the subject of the "Deviations of the Compass in Iron Ships" which appeared in NATURE of June 18 and in the last paragraph, there are statements to which I would take exception. In this paragraph the reviewer finds "food for reflection" in that, after defining C.G.S. units in the introduction of my book, I stick to inches and to other units in the text and charts.

In view of the fact that every measurement in a ship is recorded in feet and inches, whether by constructors, engineers, gunners, or navigators, to have introduced the centimetre as a common unit of measurement in the text and tables would have been a serious drawback to the utility of the book.

Again, the values on the charts of horizontal and vertical force are given in terms which have been found most convenient in the several computations, whilst not detracting from their value as exponents of the changes of terrestrial magnetism which a ship may encounter during a voyage.

Whilst introducing the student to the modern C.G.S. units, the use of the British units is too recent for neglecting to mention them, hence their retention on the map at p. 16, accompanied by the necessary multiplier for converting them to C.G.S. units if required.

A table of errata has been published for some weeks, and sent to all known recipients of the book.

June 20. E. W. CREAK.

Mercury Bubbles.

RECENTLY during the course of an experiment I had occasion to boil water in presence of mercury. After ebullition had been going on for some time, I noticed that occasionally steam forming below the surface of the mercury carried with it a pellicle of mercury as it rose through the water in the form of a bubble. When it reached the surface of the water the pellicle usually burst, and the mercury fell back as a drop. By adjusting the intensity of ebullition, it was possible to bring the two liquids into such a state that, comparatively frequently—say ten times per minute—steam bubbles covered with mercury rose through the water and floated on its surface, and, hovering there for an instant, they cooled and contracted, and sank slowly down through the water. When the bubbles are formed in rapid succession, the phenomenon is one of great beauty, as their surfaces are extremely brilliant, being formed of mercury freshly drawn out before rising into the water. The mercury used in this experiment was the ordinary commercial article, and not freshly distilled. Grease had, however, been removed from it by boiling with a solution of caustic potash. Tap water was used.

I have since found that these mercury bubbles are easily produced in a variety of ways. The most striking form of the experiment is perhaps as follows:—About 30c.c. of mercury are poured into an evaporating dish and covered by a depth of about 1·7cm. of water. Bubbles are now formed in the mercury by forcing air under its surface through a bent glass tube drawn to a fine nozzle. When the bubbles reach a certain size they become pyriform and draw out from the surface of the mercury, and, rising through the water, float on its surface. The bubbles so formed have considerable stability, and usually last for 15–30 seconds before bursting. One having a diameter of about 1·9cm. was timed to have lasted for 75·6 seconds, floating on the water. When the break does occur, it has explosive violence, and drops of mercury are thrown through a considerable distance. The bubbles which reach the surface of the water intact do not vary, as a rule, much in size, the maximum diameter observed being 2·0cm. and the minimum 1·8cm. The weight of mercury in the bubbles may be determined by floating them into a watch glass, and weighing the mercury which falls down from them on bursting. There is always more than 0·150 gram in the pellicle, and rarely more than 0·200 gram. The mean of ten weighings gave 0·177 gram as the weight of mercury in these bubbles. From these data it appears that the mean thickness of the mercurial pellicle is 0·001cm. At the thinnest part, however, it must be much thinner, for, as the profile view shows, each bubble carries a drop of varying dimensions hanging from its lower pole. The bubbles float immersed nearly to their equator. In the majority of cases they remain covered with a skin of water, so that the meniscus of the water is not depressed round the floating bubble, but is raised round it. The skin of water may be made to retreat from the upper pole, or to aggregate itself into droplets on the surface of the bubble, without causing the rupture of the bubble, by the addition of a small amount of spirit to the water. The complete absence of the water skin from the mercury pellicle may be demonstrated by the dulling of the surface of the latter when breathed upon.

The high surface tension of the water does not seem necessary to the phenomenon. Mercury bubbles in every way similar to those just described may be formed under methylated spirit, and will float upon its surface; also the addition of a slight contamination to the water, such as oil or soap or spirit, does not make the mercury film of the bubble completely unstable. But when large quantities of these impurities are added, the bubbles seldom last more than a moment on the surface of the water, although even in the presence of these impurities they may last as long as 25 seconds.

The depth of the overlying water is of importance in the ease of producing stable bubbles by this method. If it is deeper than 2cm. the bubbles usually break before getting to the surface; this is probably due to the change of pressure during the rise of the bubble through the water, and consequent excessive expansion causing rupture. If the water is less than 1·5cm. deep the bubble formed swells up to a great size (2–3cm. in diameter) before it,

leaves the mercurial surface, and generally bursts in doing so.

Considerable impurities in the mercury do not render the production of these bubbles impossible. Very stable bubbles may be formed of mercury contaminated with sodium. But the most stable have been formed from mercury recently cleaned with dilute nitric acid followed by a solution of caustic potash.

Another striking and beautiful experiment with the production of these bubbles may be made by directing a strong jet of water into a shallow vessel containing some mercury. The stream of water, carrying air bubbles with it, penetrates the supernatant water and impinges on the mercury below. There it forms numerous bubbles of various sizes contained in mercury pellicles, many of which detach themselves from the mercury below, and are carried about in the water. The stability of these bubbles is amazing. They are often whirled round and round in the turbulent motion of the water for several seconds without bursting.

Botanical Laboratory, Trinity College, Dublin.

Radium Fluorescence.

IF a tube containing radium bromide is wrapped in black paper and brought within three or four inches of the eye, in a dark room, a curious sensation of general illumination of the eye is experienced; this occurs whether the eyelid is closed or not. It is difficult accurately to describe the sensation produced; the eye seems filled with light. This effect can readily be detected when six florins are placed between the closed eye and the sample of radium.

Probably the effect is due to general fluorescence of every part of the eye, for fluorescence seems to be a commoner property of matter than hitherto suspected.

The following substances are distinctly fluorescent under radium radiation:—

Opal Glass.	Quartz.	Human Skin.
Soda Glass.	Sulphur.	Human Nails.
Lead Glass.	Sugar.	Camphor.
Uranium Glass.	Starch.	Cetaceum.
Didymium Glass.	Fluor Spar.	Solid Paraffin.
Celluloid.	Yellow Resin.	Liquid Paraffin.
Mother of Pearl.	Cotton Wool.	Turpentine.
Mica.	White Paper.	Chloroform.
Borax.	Cupri Sulph.	Water.
Alum.	Quinine Sulph.	Glycerin.

I have been unable to detect decided fluorescence in the following substances, however, with a more powerful source of radiation, or a more sensitive receiver than the eye; possibly some of these might be placed in the first list:—

Potass Bichrom.	Selenium.
Ruby Glass (flashed).	Plaster of Paris.
Prepared Chalk.	Iodosulphate of Quinine.
Ebonite.	Woods (various).
Silk.	Camphor Monobromate.

In the case of translucent substances, the effects are best observed by looking through the substance, placing the tube of radium nearly in contact with the far side. If the experiments are carried on too near the eye, the direct fluorescence of the eye itself interferes with accurate observations.

Little cups made of thick tinfoil are very convenient for the examination of liquids; the open vessel is viewed from above, the radium being placed below the cup.

It is important to well prepare the eye by excluding every trace of light from the room for at least a quarter of an hour before the experiments are made.

F. HARRISON GLEW.

156 Clapham Road, S.W., June 1.

A New Series in the Magnesium Spectrum.

IN your issue of April 16 there is an abstract of a paper communicated by Prof. Fowler on the above subject to the Royal Society. He shows that his new series is of the same type as the special series for magnesium discovered by Rydberg, and represents it by a similar formula to that used by Rydberg. But in "The Cause of the Structure of Spectra" (*Phil. Mag.*, September, 1901) I have shown that the Rydberg series for magnesium can be represented by a formula which brings out the existence of harmonics in atomic vibrations. These can be demonstrated in the hydrogen spectrum also, but it seemed to be of interest to inquire whether the new series gives a further example of the existence of optical harmonics. It does, for the vibration numbers of its four lines can be given by the formula

$$n = 39730 - \frac{107250}{(2 \cdot 977 - 2 \cdot 021/s)^2}$$

where s has the values 4, 5, 6 and 7.

This may be written approximately as

$$n = 39730 - \frac{107250}{\{3 - 0 \cdot 023 - (2 + 0 \cdot 023)/s\}^2}$$

while Rydberg's special series is represented by

$$n = 39730 - \frac{107250}{(3 - 2 \cdot 343/s)^2}.$$

I have not thought it worth while to test whether the harmonic formula for the new series is as successful as Rydberg's in giving the wave-lengths accurately, as the evidence for the existence of optical harmonics is what I wish to draw attention to. In Rydberg's series s has all the integral values from 3 to 8. In the new series Prof. Fowler gives wave-lengths for which s has integral values from 4 to 7. We might expect the lines for $s=3$ and $s=8$ to be yet found. Their wave-lengths by the harmonic formula would be 5125·8 and 3956·3.

Melbourne, May 27. WILLIAM SUTHERLAND.

THE KITE COMPETITION OF THE AËRONAUTICAL SOCIETY.

THE kite competition for the silver medal of the Aëronautical Society of Great Britain took place on Thursday, June 25, on the Sussex Downs, at Findon, near Worthing, by permission of Lord Henry Thynne. The conditions specified that a weight of two pounds as representing the weight of recording meteorological instruments should be carried, and that the medal should be given for the highest flight attained by a single kite above 3000 feet. The altitude of the kites was to be determined by trigonometrical observations.

The locality proved to be admirably adapted for the competition under the conditions of weather prevailing at the time. A light wind from the south-west blew up the slope of the Downs in the morning, and increased to a steady breeze in the afternoon, backing somewhat to the southward as the day, which was beautifully fine, went on.

It was understood that observations of the altitude of the kites should be commenced after the lapse of an hour from the signal for starting. By 2.45 p.m. stations for the kite reels had been arranged, 200 yards apart, along the slope of the Downs, and two stations for the theodolites, 700 yards apart, were selected, from which the kite stations were visible, and which were likely to command an uninterrupted view of the kites during the flight. The responsible duty of carrying out the measurements with the theodolites and the auxiliary chaining was most kindly undertaken by Mr. J. E. Dallas and Mr. W. F. Mackenzie, of the Royal Indian Engineering College, Coopers Hill, and the success of the arrangements was due in no small degree to the assistance afforded by these gentlemen.

At 2.45 the signal was given to start, and at 3.45 observations of height commenced. The synchronism of the observations of any particular kite from the two stations was secured at first by a prearranged code of signals from one theodolite station to the other, and subsequently by telephone between the two stations. Eight kites were entered for the competition, but only six appeared on the ground, and only

four reached a height sufficient to require trigonometrical determination. These were a Hargrave kite, of rhomboidal cross section, with four bands of linen, by Mr. S. H. R. Salmon; a kite of special design, by Mr. S. F. Cody, having the appearance in the air of a very large bird; a similar kite by Mr. L. Cody, and a Burmese kite by Mr. Charles Brogden.

In the course of an hour, four sets of observations were obtained for each kite, and were subsequently computed by Mr. Mason, of King's College, London, in accordance with a systematic programme drawn up by Prof. C. Vernon Boys.

As the result of the calculations, it appears that the greatest height measured for Mr. Salmon's kite was 1250 feet, for Mr. L. Cody's 1476 feet, for Mr. Brogden's 1816 feet, and for Mr. S. F. Cody's 1407 feet, and, therefore, none reached the minimum height required for the award of the medal. This unfortunate result was probably due to the fact that the wind, which had gradually increased from a light air as the sunshine continued, was a surface wind, and fell off in strength at some little height above the surface. The average heights of the several kites from the four observations of each were 1189 feet, 1271 feet, 1554 feet, and 1326 feet respectively.

At 4.45 the signal was given to haul in the kites, and all but one were safely brought back. The wire of this one had become entangled in the trees, and the kite was still in the air when the majority of the visitors had left the ground. The winding gear was in each case hand gear.

The supervision of arrangements for the competition was entrusted to a jury consisting of Dr. W. N. Shaw, F.R.S. (chairman), Prof. C. V. Boys, F.R.S., Mr. E. P. Frost, J.P., D.L., Sir Hiram Maxim, Dr. Hugh Robert Mill, Mr. E. A. Reeves, and Mr. Eric Stuart Bruce, secretary of the Aëronautical Society.

The society and its energetic secretary are to be congratulated upon having carried out successfully a series of arrangements that were necessarily elaborate, and not free from difficulties of many kinds.

THE CELTIC GOLD ORNAMENTS.

THE decision in the Court of Chancery that the gold ornaments from the north of Ireland, and bought as long ago as 1897 by the British Museum, are treasure trove, and, therefore, are to be taken from the Museum and handed over to the King, will produce a curious effect on the mind of the intelligent foreigner. But when he is told that the action at law is due to the persistent claims of the irreconcilable Irish party, he will probably begin to understand the position, from analogous conditions in his own country. The whole affair is to be regretted, but it must in fairness be stated that the entire blame lies at the door of the Irish executive, and that but for their incomprehensible apathy in making no effort to secure the ornaments before the British Museum ever entered the field, there would have been no need for a costly lawsuit. There is, however, a wider application of this particular example, arising from the contention of the Irish archæologists that all antiquities found in Ireland must remain there. Foreign students coming to an institution like the British Museum will expect to find there, primarily, an adequate representation of the archæology of the British Islands—surely not an unreasonable expectation in the central museum of the Empire. But if the Irish contention is to prevail, Scotland will claim equal rights, and Wales also when it decides on a capital for the Principality, so that the earnest student, not generally a wealthy individual, will be compelled to seek out what he wants in widely separated cities. There are, of course, arguments in favour of such a course; but, as a practical matter, there are, in fact, ancient remains enough in these islands to admit of the central museum having a fair comparative series, without in any way damaging the local museum. A little mutual understanding is all that is wanted, and it is to be hoped that the parochial idea that seems to prevail in Dublin will not be thought worthy of Edinburgh. London, after all, is the capital of these islands, and, for one foreign or English student in Dublin or Edinburgh, there are fifty, or, may be, a hundred, who work in London. The greater the number of workers, the greater will be the benefit to science.

THE UNIVERSITY OF LONDON.

THE presentation of degrées at the University of London, which took place as we went to press last week, was noteworthy in several respects. Honorary degrees were conferred for the first time in the history of the university, the recipients being the Prince and Princess of Wales, Lord Kelvin and Lord Lister; and representatives of the many and various institutions and organisations which are connected with the university, or are promoting its development, were also assembled together for the first time.

In his report on the work of the university during the year 1902–03, the principal, Sir Arthur Rücker, gave a short description of the educational scheme of the reconstituted university, beginning with arrangements which are primarily intended to be of benefit to those who are not aiming at degrees, and proceeding through the various stages of a university course to post-graduate study and research.

The following are some of the points of general interest mentioned in the report:—

Relation of the University to Schools.—The matriculation examination of the University of London has for many years served some of the purposes of a school-leaving examination. Persons who had passed it were excused by various professional bodies from their own entrance examinations; and for this or other reasons the examination was taken by many candidates who did not intend to pursue a university career. On the other hand, the Senate has for long included the examination of schools among its duties, and of late it has been felt that the time has come for performing this work on more modern lines and on an extended scale. A scheme has therefore been approved by the Senate for the inspection of schools, and the university has been recognised by the Board of Education as an authority under the Board for that purpose. This inspection will include an inquiry into the aims of the school, a consideration of its curriculum and arrangements as adapted to those aims, an inspection of the school buildings and fittings, and of the teaching work of the staff as tested by an inspection of the classes at work.

Entrance to the University.—The first matriculation examination under the new scheme took place in September last. It is a real matriculation examination in the sense that no candidate can begin his university career until he has passed it. It represents the minimum standard of admission to the university, and is intended to be such that it can be passed without special preparation or cramming by a well-educated boy or girl of about seventeen years of age.

The Senate has agreed to waive the matriculation examination altogether in the case of graduates of a large number of approved universities, and of persons who have passed the Scotch leaving examination or hold the *Zeugniss der Reife* from a Gymnasium or Real-Gymnasium within either the German or the Austrian Empire. A large number of persons have availed themselves of this privilege, which will be particularly valuable to those who may intend to supplement a degree taken at another university by study in London.

Courses of Study for Internal Students.—The distinction between an internal and an external student is that, while the latter can obtain a degree on passing certain prescribed examinations, the internal student must not only pass examinations but also produce certificates that he has attended courses of instruction approved by the university and controlled by recognised teachers.

The case of evening students has received special consideration. The hours of compulsory attendance are reduced in the case of those who submit certificates that they are engaged in some business occupation for twenty-five hours a week. The time required for the complete course varies with the subjects chosen, but in general the reduction allowed makes it possible for a student giving some three evenings a week to attendance on lectures and laboratories to complete a degree course in four years. It is satisfactory to be able to state that the regulations under this head are working smoothly at the polytechnics.

Organisation of Teaching.—It is not, however, only by curricula and arrangements as to examinations that the work of a teaching university must be carried on. It is also necessary to extend, organise, and coordinate the work of the teachers. This task requires funds, and also the cooperation of the various schools and other institutions connected with the university.

The Senate has approved a scheme for the establishment in the neighbourhood of the university of an institute of preliminary and intermediate medical studies, which has the support of the Faculty of Medicine, and has authorised the issue of an appeal for its building and endowment. When this is carried out, some, at all events, of the medical schools will be relieved of the necessity of maintaining independent courses of instruction on subjects which are only ancillary to medicine, and need not be studied in the immediate vicinity of a hospital. For the realisation of this project a large sum of money is required, but there can be no doubt that it will be an addition of the first importance to the equipment of London as a centre of medical study.

The attention of those interested in the teaching of engineering has been drawn to the proposals made by Mr. Yarrow in support of the system by which students of that subject spend alternate periods of six months in a college and the workshops. It is satisfactory to be able to state that in all probability some of the schools of the university will cooperate with employers in introducing into the metropolis a system of technical education which has worked well elsewhere.

Lastly, it may be added that the negotiations between the university and University College for the incorporation of the college in the university have been brought to a successful conclusion, and a joint committee has been appointed to draft a Bill for giving effect to the agreement. University College has purchased a plot of land in the neighbourhood of the hospital, to which the medical school will be transferred on an independent footing. This step is a necessary preliminary to incorporation, as it is not considered to be desirable that the university should itself control one, and one only, of the numerous medical schools which exist in London.

Post-graduate Work and Research.—The physiological department of the university, which is established in the university buildings, has been at work throughout the year under the direction of Dr. Waller, F.R.S., who has devoted the whole of his time to the interests of the laboratory. It will be remembered that all the principal teachers of physiology in London have banded themselves together to give, in turn, lectures to post-graduate students.

The research work carried on in the laboratory has resulted in the production of eight or ten original papers, which have appeared in English, American, and German periodicals.

The excellent example given by the physiologists has been followed by the botanists, who have in like manner agreed to give courses of post-graduate lectures at the Chelsea Physic Garden, a scheme which has only been made possible by the cordial cooperation of the trustees of the City Parochial Charities.

Gifts to the University.—The first year's payments on account of the grant of 10,000*l.* a year from the Technical Education Board of the County Council have been made, and the various professors and lecturers have been appointed and are now at work.

The Worshipful Company of Goldsmiths has presented to the university the very valuable library of pamphlets and other works relating to economics, collected by Prof. Foxwell, and recently purchased by the Company at a cost of 10,000*l.* To this munificent gift the Company has added considerable sums to aid the university in installing and maintaining the library.

During the year, Mr. G. W. Palmer, M.P., has contributed the sum of 1000*l.* towards the endowment of the physiological laboratory, and Mr. Alfred Palmer has made a contingent promise of a like amount for the same object.

In addition to their former munificent promise of 30,000*l.* in aid of the incorporation of University College in the university, the Worshipful Company of Drapers has presented 1000*l.* to the university, and a scheme is being drafted for the application of this grant to University College.

Apart from the grant of the Technical Education Board of the County Council, about 25,000*l.* has been given to the university by the above-mentioned donors in the course of last year.

Summary.—The foregoing report will, it is hoped, prove that the university is anxious to leave no part of its duties unfulfilled.

New avenues of work have been opened in connection with schools, with university extension, with the colleges, medical schools, and polytechnics; students are entering both for the ordinary matriculation examination and for post-graduate study and research in unexpected numbers. The authorities of the institutions connected with the university have in all cases shown the most anxious desire to work in harmony with it, and to arrange their classes to meet the conditions which the Senate has laid down.

But, while there are many grounds for hope, and while the university is doing its best to make itself worthy of public support, it must be frankly admitted that it can never adequately fulfil its duties without the supply of funds from public or private sources on a very large scale. The incorporation of University College cannot be carried out until another 100,000*l.* has been raised; the complete endowment of the Institute of Medical Sciences would need much more than that amount; the fuller organisation of teaching on lines which have been already adopted in the case of German, and towards which a small beginning has been made in the case of chemistry, would require very large sums. On the one hand, technical instruction is sorely in need of development; on the other, if funds were available, a scheme could be worked out by which students of literature and archæology might make full use of the magnificent libraries and collections which London possesses.

Lastly, the payment of the professors, which is in many cases very inadequate, and of the cost of their departments, depends so much upon fees and so little upon endowments that the expense of education in London is comparatively high. Those who are engaged in the work are convinced that the one thing needful is endowment adequate to make good the apathy of the past, and to secure the promise of the future. It is for London to say whence and when that endowment will be forthcoming, and to determine whether a university which is providing for all learners, from the evening student to the candidate who has already graduated elsewhere, shall control means and appliances worthy of the highest educational institution in the capital of the Empire.

After the Prince of Wales had been presented for the honorary degree of doctor of laws and the Princess for that of doctor of music, Prof. Tilden, Dean of the Faculty of Science, presented Lord Kelvin for the degree of doctor of science, and in doing so he said:—

My Lord the Chancellor, I present to you William Thomson, Baron Kelvin of Largs, for the degree of doctor of science, *honoris causa*. The illustrious son of a family famous for mathematical talent, for more than half a century Lord Kelvin filled the office of professor of natural philosophy in the ancient University of Glasgow. Two generations have passed since he entered on his professorship, and the advances in physical science which have distinguished the nineteenth century from all preceding epochs have been largely due to the influence of Lord Kelvin in promoting true ideas concerning the conservation of energy, the laws of thermodynamics, and their application to the

mechanics and physics of the universe. His untiring intellectual activity has led him also to inquire into problems interesting to the chemist and geologist, as well as those which are important to the physicist and engineer. He has calculated the probable size of atoms; he has studied the structure of crystals; he has estimated the age of the earth. But the world knows him best as the man who has shown how practically to measure electrical and magnetic quantities, and has made it possible to link together distant continents by the electric telegraph. It is he who has shown how to neutralise the effects of iron on the compasses of ships and how to predict the tides, and who has thus taught the mariner to steer safely over the surface of the ocean and to sound, as he goes, its depths and shallows. A greater philosopher than Democritus, in him are united the qualities of Archimedes and Aristotle. Regarded with affectionate reverence by his contemporaries, it cannot be doubted that his name will shine brightly through long future generations. In offering a place of honour to such a man the university confers lustre on itself.

Mr. Butlin, Dean of the Faculty of Medicine, then presented Lord Lister for the honorary degree of doctor of science in the following terms:—

My Lord the Chancellor, since the reconstitution of the university, the Faculty of Medicine has been almost continuously engaged in arduous and not always pleasant work, and to-night, as if in compensation, there falls to its lot—for I am but the mouthpiece of the faculty—the agreeable task of presenting my Lord Lister for one of the four first honorary degrees of the University of London. While every person in my profession is familiar with the work which he has done, and his name has become a household word in every part of the civilised world, comparatively few persons are acquainted with the obstacles which he has overcome. It is not only that, sitting down many years ago in front of a difficult problem of pathology, Lord Lister solved the mystery which had puzzled the brains of the greatest surgeons of all time, or that he then invented a means of meeting and overcoming surgical infection, but that he stood by his theory, and fought manfully for it, until at length, in spite of opposition, of envy, of lack of faith, and even of ridicule, he succeeded in carrying conviction to the minds of his own profession and of the world at large. And all this was done, and these things were borne, not for the sake of gain—care for which has never been a part of Lord Lister's character—but for the sake of science and for the relief of human suffering. It is well-nigh impossible for those among whom a great man lives to form a just estimate of the value of his work, whether in art or in science, but I venture to predict that the name of Lord Lister will be handed down from generation to generation, from century to century, until, more than 2000 years hence, he will be acknowledged by our descendants as the father of surgery, in like manner as Hippocrates is regarded by this present generation as the father of medicine. I, therefore, sir, beg to present the Right Hon. Lord Lister, and ask you to confer on him the honorary degree of doctor of science, and I do so with the happy confidence that the addition of his name will confer lustre now and in the future on the University of London.

The students who had gained degrees in various faculties of the university were then presented in groups by the Dean of each faculty.

A CHARLOTTENBURG INSTITUTE FOR LONDON.

THE magnificent proposals which Lord Rosebery laid before the County Council in his letter to its chairman, Lord Monkswell, on June 27 have roused feelings of keen interest and high hopes in many who, for years past, have been crying, as it seemed in the wilderness, to the nation, to the Government, to public bodies, and to private individuals to do something to improve our higher technical educational methods. Generally speaking, the cry has been ignored or else met with the reply that our fathers obtained the command of the sea, extended our commerce and made the country the greatest commercial centre of the world, so surely methods which were good enough for them are good enough for us. Passing strange, but were they content with the methods of *their* fathers? did the eighteenth century show no advancement upon the seventeenth century? At the beginning of the nineteenth century we were ahead of all nations in the use of gas as an illuminant; later on, our railway systems and our steamships became the envy of the world; other nations could not approach us in engineering. In the middle of the century we were pioneers in many chemical discoveries; but then, apparently, so much prosperity and success seems to have been too rich a diet, and we waxed fat and kicked.

Of late years the country has felt more and more the competition of other nations. The colour industry has forsaken our shores, the finest electrical machinery is made abroad, we go to America for labour-saving appliances. Thinking men have cast about and tried to find a reason why other nations should take our markets; but when it was first suggested that our deficiency in scientific and technical education was at the root of the matter, those who dared to make the suggestion were, if not mocked at, at any rate treated with scant courtesy.

Now, however, it is generally admitted that, unless we improve our educational methods, we shall fall behind in the modern race for advancement to such an extent that it will require almost a miracle for us to be able to pull up again.

Our secondary education is not what it should be, but it is gradually improving. Technical education, generally speaking, has been tinkered at. The polytechnics are doing good work, but they are largely engaged in turning out better workmen and foremen workmen, or taking the place of the old apprenticeship system. Lord Rosebery now comes forward, and, through the generosity of Messrs. Wernher, Beit, and Co. (who offer 100,000*l.*) and other large business houses, is able to offer to London the means for providing higher technical education. Briefly stated, the idea put forward is to supply London with a technical college after the lines of the world-renowned polytechnic at Charlottenburg, which represents the acme of technical education. It is not for teaching the elements of this or that science; but when the foundation of a thorough education has been laid, students can go there for the building up of the superstructure. It is not an easy matter for a student to gain entrance into the Charlottenburg Institute. A very thorough examination must first be passed, in order to show that he is capable to take advantage of the instruction offered.

The Charlottenburg Institute cost more than 500,000*l.* to build and equip, and entails an annual outlay of 55,000*l.* The offer made by Lord Rosebery to the County Council is one of 300,000*l.* to build the institute, and he has reason to think that the Commissioners of the 1851 Exhibition will grant the site (some four acres of ground). The County Council is asked to contribute 20,000*l.* a year for the maintenance of the institute. This sum may be sufficient at the commencement, but will probably be inadequate as the place becomes known and its value appreciated.

Is it right that the County Council should be asked to find the money? The institute is meant to be imperial. Londoners may and will attend it; but it is hoped by the donors of the funds that students from all parts of the British Empire will flock there, and thus make London, "at any rate, so far as advanced scientific technology is concerned, the

educational centre of the Empire." Lord Rosebery considers it "little short of a scandal that our own able and ambitious young men, eager to equip themselves with the most perfect technical training, should be compelled to resort to the universities of Germany or the United States." Why, then, should London, which is already overtaxed, and has much more yet to contribute to primary and secondary education, be called upon to pay for the upkeep of this great Imperial undertaking? Are our legislators so dead to the interests of the nation that they will refuse—if asked—to support such a scheme? or to find the much larger sum which will be required for the development of London University.

Lord Rosebery has agreed to act as the first chairman of the trustees. Presumably they will appoint a committee to advise and help them in drawing up and settling the scheme. It is to be hoped that they will use every endeavour to choose the right men, men who are thoroughly conversant with the needs of the nation, and who understand what technical education is.

The institute, if properly organised and equipped, will be a national gain, a national asset; if run on wrong lines a national loss. But with the magnificent institutes in Germany to adapt from, there is really no reason why it should not be a grand success. One thing, however, should not be forgotten, a splendid equipment without an equally good curriculum and organisation is almost valueless. It must also be remembered that the scheme does not touch the question of the provision for development required by the University of London.

The scheme outlined in Lord Rosebery's letter may, we hope, be taken as a sign that our great manufacturers are becoming aware of the national advantages to be derived from an alliance between science and industry. The meeting held at the Mansion House on Monday to inaugurate a memorial to the late Sir Henry Bessemer gave additional reason for the belief that an awakening is taking place. It was decided that a memorial should be established which should not only commemorate Bessemer's work, but also provide a means of carrying it on to further achievements. The proposals of the memorial committee, which were read at the meeting on Monday, include the provision of well-equipped mining and metallurgical laboratories, and scholarships for post-graduate study in London. In the words of the committee:—

> The establishment of completely equipped metallurgical teaching and research works in London will form the first object of the memorial, for which the practical cooperation and financial aid of the industrial world is asked. The primary aim will be the thorough technical instruction of mining and metallurgical students. Metallurgical tests and research of all kinds, for which facilities are not available in Birmingham or Sheffield, will be carried out at these works, on a practical scale, by engineers and others. In this way advanced students will be afforded opportunities for the acquirement of practical knowledge and for original research which it would be difficult to obtain in any other way. The second object of the memorial will be a system of grants, in the form of scholarships, for post-graduate courses in specialised practical work in London and the great metallurgical centres.

In proposing the adoption of this form of memorial, Mr. Haldane said the work which was to be done in teaching by the Bessemer Foundation should form a part—an integral part—of the larger scheme for raising the nation's efficiency. He had reason to know that the King was fully cognisant of the details of the great scheme which was laid before the public in Lord Rosebery's letter, and that His Majesty had also been informed of the proposal to launch the Bessemer memorial scheme in connection with and as an integral part of it.

The committee's proposals were adopted, and there is little doubt that the support which will be given to them will enable provision to be made for study and research in mining and metallurgy on a scale appropriate to Bessemer's great name, and to our responsibilities as a State. To maintain a leading position among the nations of the world, industrial methods must be developed in directions indicated by scientific research, and the recognition of this fact in the scheme for the proposed Charlottenburg Institute for London, and in that of the Bessemer Memorial Committee, will give satisfaction to all who are familiar with the developments due to the application of science to industry.

THE BRITISH ACADEMY.

THE first anniversary meeting of the British Academy was held last week. We have received no report, but we learn from the *Times* that the objects of the Academy, and the studies to be fostered by it, were described in the presidential address. In the course of this address, Lord Reay remarked:—

> The Academy might be regarded as embodying the recognition on the part of England that she, too, at last recognised that history, philosophy, philology, and kindred studies call for the exercise of scientific acumen, and must take their place by the side of the sister sciences, the priestesses of nature's mysteries.

We are all anxious to extend the boundaries of knowledge by scientific study, and Lord Reay appears to have overlooked the fact that the Royal Society was founded for the purpose of promoting the progress of the subjects he mentions, among others. The first charter granted to the Royal Society in 1662 contains the following words:—

> We have long and fully resolved with Ourself to extend not only the boundaries of the Empire, but also the very arts and sciences. Therefore we look with favour upon all forms of learning, but with particular Grace we encourage philosophical studies, especially those which by actual experiments attempt either to shape out a new philosophy or to perfect the old.

The recognition of the value of the application of scientific principles to all inquiries is therefore as old as Charles II., and has not recently been discovered as Lord Reay seems to suggest.

Lord Reay remarked that it would be one of the first important duties of the Academy with the Royal Society to prepare a fitting welcome for the International Association of Academies when it meets in London next year at Whitsuntide, and to make that meeting a success. The following points from the address show some of the directions in which the Academy is to work:—

> In history we have to deal with the mutual interaction of different civilisations, and to compare these civilisations. The task of the historian is very similar to that of the explorer of nature's laws. Our colleague, Prof. Bury, in his interesting inaugural lecture, has eloquently emphasised the application of strict scientific methods to the study of history, as the study of "all the manifestations of human activity." In the department of archæological exploration an understanding might be obtained through the International Association with regard to the spheres of scientific exploration which should be allotted to various nations, so as to arrive at a systematic distribution of archæological research in the vast domain open to the explorers of different nationalities. Many questions belonging

to economic science have to be studied. The scientific treatment of law has been neglected in England, and it will be our privilege to give encouragement to those who are striving to place the scientific study of law on a footing worthy of the great traditions of English jurisprudence. We shall approach the problems connected with education in a philosophical and historical spirit. Our charter imposes on us the duty of dealing with questions which embrace the whole range of the moral sciences. We have to deal with the problems of the mind. The complex agencies which constitute the motives of our actions are subjects of our investigation. The forces which influence individual energy are open to our analysis. To discover the principles which regulate the progress of human society, which eliminate the causes of friction, which facilitate the attainment of high ideals, all these inquiries come legitimately within the sphere of our operations. The unbiased attitude of the mind towards ethical and metaphysical problems is one of the conditions of our existence as a scientific body. The tendency of all scientific study is to become international and cosmopolitan. We may compare our Academy with a national clearing-house, and the International Association of Academies to an international clearing-house of ideas on these subjects.

NOTES.

THE names of a few men distinguished by their contributions to scientific knowledge are included in the list of birthday honours. Dr. W. D. Niven, F.R.S., has been promoted to the rank of Knight Commander of the Order of the Bath (K.C.B.). Dr. David Morris, F.R.S., and Dr. Patrick Manson, F.R.S., have been promoted to the rank of Knight Commanders of the Order of Saint Michael and Saint George (K.C.M.G.). The honour of knighthood has been conferred upon Dr. P. H. Watson. Mr. F. W. Rudler has been appointed a Companion of the Imperial Service Order.

THE Colombo correspondent of the *Times* reports that on a motion introduced in the Legislative Council on June 24, the Government of Ceylon agreed to invite the British Association to Colombo in 1907 or 1908.

DR. C. J. MARTIN, F.R.S., professor of physiology in the University of Melbourne, has been appointed director of the Jenner Institute of Preventive Medicine.

IN reply to a question asked in the House of Commons on Tuesday, it was announced that, in the first instance, the following six lightships are to be connected with shore stations by wireless telegraphy:—the East Goodwin, the South Goodwin, the Gull, the Tongue, the Sunk, and the Cross-Sand.

MANY friends of the late Sir William Roberts-Austen will be glad to know that it is proposed to erect a memorial in his honour in the Church of St. Martins, Blackheath, Wonersh, where he resided for many years. The erection of the church was mainly due to his generous and devoted efforts, and he often said that the first things done to complete the building should be to line the east wall and the chancel arch with marble or alabaster. It is proposed that the memorial should include the carrying out of this work, and the erection of a memorial tablet or inscription in the church. Contributions for this purpose should be sent to Mr. H. W. Prescott, Brantyngeshay, Chilworth, Guildford.

M. ZYBIKOFF, a Buddhistic Buriat of the Baikal region and a graduate of the University of St. Petersburg, has recently returned to Russia after a year's residence in the city of Lhassa. M. Zybikoff was able to travel in Tibet as a Lama, and approached Central Tibet by way of the Boumza Mountain, where Przewalsky was turned back in 1879. He describes the city as one of not more than ten thousand inhabitants; the Uitchu River passes to the south, canals and dykes protecting the city itself from floods. The residence of the Dalai Lama is on Mount Buddha La, a mile from Lhassa. Near it is the ancient castle of Hodson Buddha La, a structure 1400 feet long and nine storeys high, containing the treasury, the mint, quarters for officials and monks, and a prison. The native traders are all women.

MRS. GARRETT ANDERSON, M.D., in a letter to the *Times*, directs attention to the work of the Imperial Vaccination League, which has now been in existence a year. The League, which has on several occasions been referred to in these columns, was formed to study the administration and working of the "Vaccination Act," 1898, and to promote vaccination, and especially revaccination, among the public. It is now desired to extend its sphere of work by assisting candidates at Parliamentary elections to meet the pressure brought to bear upon them by the opponents of vaccination. For this purpose Mrs. Anderson appeals for subscriptions, and desires to find 100 friends who will each contribute five guineas a year for three years. The League has done good work in the past, and it is to be hoped that this useful extension will receive support.

ATTENTION was directed in the House of Commons last week to the administration of the "Cruelty to Animals ('Vivisection') Act," 1876. The debate was more moderate in tone than some previous ones on the same subject, and had for its main object the imposition of more stringent inspection by the appointment of additional inspectors. Sir M. Foster and Dr. Hutchinson strongly deprecated the attacks on, and abuse of, the medical profession with regard to this question, and obtained a retractation from Mr. MacNeill. The Home Secretary, in his reply, defended the inspections as carried out by Dr. Thane, and pointed out that successive Home Secretaries had been among the severest critics of vivisection, and that his own control was exercised with the greatest care and full appreciation of his responsibility. It would be almost impossible to improve upon the administration of the Act, and he doubted whether the ability of the inspectors was sufficiently recognised or remunerated.

REUTER reports that a violent earthquake occurred at Erlau, Hungary, on the morning of June 26. Four shocks were felt. Several houses in the suburb of the town collapsed, and nearly all the buildings in the town were damaged.

THE arrangements for the International Fire Prevention Congress, convened by the British Fire Prevention Committee, have now been completed. The congress will be conducted in general and sectional meetings; there will be six sections, each of which will have its own honorary chairman and acting vice-president. The sections with their honorary chairmen will be as follows:—(1) Building construction and equipment, Privy Councillor J. Stubben; (2) electrical safeguards and fire alarms, Chevalier Goldoni; (3) storage of oils and spontaneous combustion, M. Louis Bonnier; (4) fire survey and fire patrols, Prince Alexander Lvoff; (5) fire losses and fire insurance, Mr. C. A. Hexamer; (6) fire tests and standardisation, M. Alcide Chaussé. All meetings, except the opening meeting, will be held at the Caxton Hall, Westminster, and the whole of the executive arrangements will be in the hands of Mr. Edwin O.

Sachs, as congress chairman, with Mr. Ellis Marsland as honorary general secretary. The general opening meeting will be at the Empress Theatre, Earl's Court, lent by the executive of the International Fire Exhibition. The subject-matter is limited strictly to fire preventive questions, and all internal fire brigade questions will be excluded, as these will be dealt with at separate meetings.

A PARIS correspondent writes:—M. Santos Dumont's experiments in aërial navigation in Paris during the past fifteen days have attracted public attention. M. Santos Dumont was seen flying over the Longchamps Hippodrôme when a race was actually going on; at another time he went to his private residence in the Champs Elysées, left his balloon to the care of his assistants, who had followed his aërial track in an automobile, took his customary breakfast, and returned to the balloon shed near Puteaux Gate, in the Bois de Boulogne. On another occasion he sailed from the Puteaux Gate to Bagatelle, where he landed during a parade. But the area of his promenades is very limited, and sometimes the balloon has to be carried by hand for a part of the way; so it is not possible to say if M. Santos-Dumont has really improved his speed and stability.

THE fifty-sixth annual meeting of the Palæontographical Society was held at the Geological Society's apartments, Burlington House, on June 27. The report of the council referred to the activity of the contributors to the Society's monographs, which extended over a wider field than usual. Volumes on Pleistocene Mammalia, Carboniferous and Cretaceous fishes, Carboniferous and Cretaceous Mollusca, Trilobites, Graptolites, and Devonian corals were in course of publication. The expenditure for the year exceeded the income, which was nearly 100*l.* less than that of the preceding year. The withdrawal of several small libraries was referred to, and an appeal for new personal subscribers was made. The officers were re-elected, Dr. Henry Woodward as president, Mr. Etheridge as treasurer, and Dr. Smith Woodward as secretary.

TWELVE stations took part in the international scientific balloon ascents on the morning of May 7, including Zürich, for the first time, and Bath. The records for the latter station had not been found at the time of the publication of the preliminary results. The following are the most noteworthy of the unmanned ascents:—Strassburg, 13,400 metres; at 9500 metres the temperature was $-58^{\circ}\cdot3$ C., above this height an inversion of temperature occurred. The reading at starting was $10^{\circ}\cdot5$. At Berlin the balloon rose to 13,360 metres, temperature at 7560 metres was -43°, at starting $11^{\circ}\cdot9$. At Vienna a temperature of $-54^{\circ}\cdot4$ was recorded at 9020 metres, at starting $14^{\circ}\cdot8$. At the first two places the ascents were made about 4h. a.m., at Vienna about 7h. a.m. Relatively high pressure prevailed over south-east Europe, and a large area of low pressure to the northward, with its centre (29·5 inches) over the North Sea.

THE Meteorological Office pilot chart for July contains, in addition to the usual information, a most useful series of twelve maps exhibiting the direction of flow of the tidal streams round the British Isles at each hour from high water at Dover. They are reduced from the more detailed large Admiralty charts in three volumes of 36 sheets. To seamen the handy form in which the streams are now shown on the pilot chart will be invaluable, as the whole circulation is seen at a glance. Early in April last it is shown, by means of a small map, that there was a remarkable displacement of the Atlantic anticyclone, which was transferred northward beyond the 50th parallel. As a result, the Transatlantic liners, to and fro on the northern routes, experienced easterly winds right across the ocean, instead of the usual westerly and south-westerly winds. There were numerous reports of ice during May and the early part of June.

THE German Government has erected a new lighthouse on the island of Heligoland, which will supplant the old petroleum lamp that has long directed the commerce at the mouth of the Elbe. It is claimed for this light that it is one of the most powerful in operation. The distinguishing feature is the return that has been made to the old form of parabolic reflector, with a powerful illuminant in the focus, in place of the Fresnel lenses and prisms. The mirror in this case is of glass, 75cm. in diameter, and silvered at the back. An arc light with a current of 34 amperes is the illuminant. The positive pole of the carbon is so near the focus that it is estimated that the beam is not more than two degrees in diameter, and its candle-power is quoted as thirty millions. No protection against weather is provided in front of the light, and it is asserted that none is needed. Three similar mirrors and lamps are mounted in one plane round an axis, and the whole revolves four times in a minute, so that a flash is given every five seconds. A fourth mirror and lamp is provided in case of necessity, which will turn three times as rapidly, but it is not proposed to use this except in case of emergency. The duration of the flash is only one-tenth of a second. Herein the German firm of Schuckert and Co., the manufacturers, have followed the lead of the French authorities. It is, however, a question whether these brief durations have not been carried to an extreme. Undoubtedly one-tenth of a second is sufficient to make the maximum impression on the eye, when the light is brilliant. But with a hazy atmosphere, and the light much diminished, it is doubtful whether a longer duration should not be allowed. The experiment will be watched with great interest, both on account of the bold deviation from the ordinary plan which has been so long followed, and also on the ground of economy, which is claimed for the new method. It is stated that on the first night of trial the light was seen at the pier of Büsum, a distance of 64 kilometres, or 40 miles.

"THE Cure of Consumption," a popular account of the open-air treatment of pulmonary tuberculosis, and a description of "An Experiment in Nature-study," carried out among village lads, are two articles of scientific interest that appear in the current issue of the *Pall Mall Magazine*.

SEVERAL cases of fatal illness have occurred in connection with the Mond process for the extraction of nickel from its ores, which is based upon the conversion of the metal into gaseous nickel carbonyl. It is not yet known whether the nickel carbonyl is itself poisonous, or whether some other deleterious gas or substance is generated in the process, but the subject is being investigated by several experts.

THE statistics of the anti-rabic inoculations carried out at the Pasteur Institute, Paris, during 1902 have just been published. The number of persons treated was 1106, of whom three died, but one of these had not completed the treatment, leaving 1105 cases with two deaths, a mortality rate of only 0·18 per cent. This is the lowest mortality rate recorded since the commencement of the treatment in 1886.

THE new method for sewage disposal by bacterial treatment in a septic tank is not altogether free from danger. In this process the sewage is stored in closed tanks for a variable period, during which time it is acted upon and dissolved by the agency of the bacteria present. Probably

marsh gas and other gases are generated which become explosive when mixed with oxygen and fired. During the past six months three explosions of septic tanks have occurred, viz. at Exeter, Walton-on-Naze, and Sheringham; in the last named three persons were killed and several injured.

A PARLIAMENTARY paper has been issued by the Colonial Office containing official correspondence and circulars relating to the investigation of malaria and other tropical diseases, and the establishment of schools of tropical medicine. It contains a circular letter to the Governors of all colonies upon the investigation of tropical diseases and the establishment of the London School of Tropical Medicine, a summary of researches upon malaria by Drs. Stephens and Christophers, a despatch from Sir William MacGregor relating to the prevalence and prevention of malaria at Ismailia, and a despatch from Sir F. A. Swettenham upon the work done at the Institute for Medical Research, Federated Malay States. The increasing importance of the study of tropical medicine has been recognised by the Special Board of Medicine of Cambridge University, which has proposed to institute a special examination and to grant a diploma in tropical hygiène and medicine.

A PAPER read before the Royal Dublin Society by Dr. H. H. Dixon offers a reply to some criticisms passed on the cohesion theory of the ascent of sap which was proposed by the author and Dr. Joly. There seems to be a difficulty in the minds of some botanists in accepting this hypothesis if the column of water contains air-bubbles. As Dr. Dixon points out, this merely puts out of gear the particular cell in which the bubble appears. Another opinion which the author combats is that glass tubes containing plaster of Paris through which water passes may be taken as the equivalent of the water columns in trees. Experiments show that plaster continues for a long time to absorb water, and further, the amount varies with the changes of temperature.

THE appearance of a new scientific publication, *Records of the Albany Museum*, emanating from Grahamstown in South Africa is a matter for congratulation, whether it is offered to the director, Dr. Schönland, or in so far as it furnishes an indication of the sign of the times. Dr. R. Broom contributes three palæontological articles, in the first of which he describes the skull of a small lizard taken from the Triassic beds in South Africa. Dr. Schönland is responsible for the remainder of this, the first part. A critical account of a number of species of South African aloes adds considerably to the information collected by Mr. J. G. Baker in his monograph in the "Flora Capensis." In addition to the botanical papers, Dr. Schönland describes some Bushman and Hottentot pottery which is stored in the museum. A pot about 14½ inches high, consisting of a wide neck slightly ornamented by raised lines and a remarkably fine curved base, approximately oval, denotes workmanship of a higher order than that displayed by the civilised potter.

WE have received the second part of the *Sitzungsberichte* and *Abhandlungen* of the Dresden "Isis" for 1902. The former contains an obituary notice of the late Hofrath Dr. H. Nitsche, professor of zoology at the Academy of Tharandt. Among the contents of the latter is an article, by Prof. O. Schneider, on the prevalence of melanism among the beetles of Corsica.

AN interesting case of "commensalism" is recorded by Dr. R. Horst in the May issue of the Leyden Museum *Notes* (vol. xxiii. part ii.). In Sabang Bay, Poeloe Weh, several small fishes (*Amphiprion intermedius*) were observed to issue from the cavity of a large anemone of the genus Discosoma. Several previous instances of a similar association are on record, notably in Australian waters, where other species of Amphiprion have been observed frequenting anemones of the genus above mentioned.

OUR knowledge of the fishes of Africa is progressing by rapid strides, one of the latest contributions to the subject being a paper on a collection from Zanzibar, by Mr. H. W. Fowler, published in the *Proceedings* of the Philadelphia Academy, in the course of which two species are described as new. The same serial also contains a revision of the land and fresh-water molluscs of Western Arkansas and the adjacent States, by Mr. H. A. Pilsbry.

WE have received a copy of the address on "Modern Views on Matter: the Realisation of a Dream," delivered by Sir William Crookes before the recent Congress of Applied Chemistry at Berlin. A general account of the proceedings of the congress appeared in NATURE of June 18 (p. 156), and abstracts of some of the papers brought before the various sections are given in the present number.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mr. H. Padgett; two Two-spotted Paradoxures (*Nandinia binotata*) from West Africa, presented by Mr. Charles R. Palmer; a Burrowing Owl (*Speotyto cunicularia*) from South America, presented by Mr. L. M. Seth-Smith; a Diademed Sand Snake (*Lytorhynchus diadema*), five Egyptian Eryx (*Eryx jaculus*) from Egypt, two Bull Frogs (*Rana cotesbiana*) from North America, deposited; six American Flying Squirrels (*Sciuropterus volucella*) from North America, purchased; an Ogilby's Rat Kangaroo (*Bettongia penicillata*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

REPORTED CHANGE ON SATURN.—The following telegram, announcing the discovery of a new phenomenon on Saturn by Prof. Barnard, has been received from the Kiel Centralstelle:—

"Conspicuous white spot, Saturn, three seconds north, transit June 23, 15h. 47·8m., Williams Bay time.—Barnard."

SEARCH EPHEMERIS FOR FAYE'S COMET.—A search ephemeris for Faye's comet, from which the following is an extract, is published in No. 3876 of the *Astronomische Nachrichten* by Prof. E. Strömgren:—

Ephemeris 12h. (Berlin M.T.).

1903	α h. m. s.	δ ° ′	$\log r$	$\log \Delta$
July 2	4 59 44	+18 41·8	0·2240	0·4060
„ 6	5 11 28	+18 42·6		
„ 10	5 23 6	+18 40·2	0·2281	0·4044
„ 14	5 34 37	+18 34·7		
„ 18	5 46 0	+18 26·1	0·2330	0·4028
„ 22	5 57 14	+18 14·5		
„ 26	6 8 19	+18 0·0	0·2386	0·4012
„ 30	6 19 13	+17 42·8		

This ephemeris is calculated from the elements previously published, in the *Astronomische Nachrichten*, by the same worker, and takes June 3·64 (Berlin M.T.), 1903, as the time of perihelion passage. The comet will rise about two hours before sunrise towards the middle of the month.

OBSERVATIONS OF NOVA GEMINORUM.—Prof. Barnard publishes in No. 5, vol. xvii., of the *Astrophysical Journal*, the results of his observations of Nova Geminorum; most of these observations were made with the finders of the 40-inch and 12-inch refractors of the Yerkes Observatory.

During the first set of observations the Nova had a strong reddish colour, but this has since disappeared,

Observations made in order to determine whether the light of this Nova exhibited the change of focus observed in the light of Nova Persei gave at first, negative results, but careful observations made on April 27 indicated that the light of the Nova, when compared with that of an ordinary star, showed a difference of +0·08 inch (2·00mm.) in focus.

The crimson image observed on March 30 had disappeared on April 27, the out-of-focus image of the Nova then resembling that of an ordinary star. Cloudy weather at Yerkes from April 7–27 prevented Prof. Barnard from determining the exact date at which this change took place. The magnitude of the Nova is exhibiting the same periodical fluctuations as were observed in the case of Nova Persei.

THE RED SPOT ON JUPITER.—In No. 3875 of the *Astronomische Nachrichten*, Mr. Stanley J. Williams describes, and gives the detailed results of, his observations of the "great red spot" during the opposition of 1902.

Transit observations of the middle of the spot gave a rotational period of 9h. 55m. 39·55s., and of the "following" end of the spot 9h. 55m. 39·88s.; taking the weighted mean of these observations, Mr. Williams obtains, from 275 rotations, 9h. 55m. 39·66s. as the result. This shows a further considerable acceleration of the rotational period of the red spot, amounting to 1·26s., as compared with the result obtained during the opposition of 1901.

THE STUDY OF VERY FAINT SPECTRA.—In a dissertation published in No. 35 of the Lick Observatory *Bulletins*, Mr. Harold K. Palmer describes an arrangement whereby the Crossley reflector has been adapted to the study of very faint stellar and nebular spectra.

The work was first suggested, but not completed, by the late Prof. Keeler for the purpose of obtaining, amongst other spectra, the spectrum of the faint central star of the ring nebula in Lyra.

A modified form of Prof. Keeler's proposed spectroscope has now been adopted, and the results obtained with it are very satisfactory; its essential features are as follows:—A concave quartz lens intercepts the converging beam of light from the large mirror, and renders the rays parallel; these parallel rays are then refracted by a 50° quartz prism and are focused on to the photographic plate by a convex quartz lens placed between the prism and the plate. The two lenses and the prism each have an aperture of 25 mm. An arrangement attached to the prism cell allows the prism to be moved to one side, so that the spectroscope may be focused for the incident light by means of an eye-piece which carries a finely divided scale, and another eye-piece, placed at the side of the movable slipping plate, allows the "following" during exposure to be performed in the usual manner.

Spectrograms of such faint objects as the stellar nebula NGC 6807 (magnitude 13), the Novæ in Perseus (1901), Auriga and Cygnus (1876), and the Wolf-Rayet star No. 43 have been obtained with exposures varying from one to four hours, and show a fair amount of detail.

Three spectrograms of the ring nebula were obtained, two with thirty minutes' and one with two hours' exposure, but the only trace of the central star is a faint line which appears on all three plates, and, in the longer exposure, shows a faint dot in a position a little to the more refrangible side of the condensation λ 373 in the nebula ring. A detailed description of each of the spectra obtained is given in Mr. Palmer's paper.

INSTITUTION OF NAVAL ARCHITECTS.

THE Institution of Naval Architects held its summer meeting this year in Ireland, commencing Tuesday, June 23, when the opening meeting was held in Queen's College, Glasgow, the president of the Institution occupying the chair.

After the usual formal proceedings, in which the members were welcomed to the city by Sir Daniel Dixon, the Lord Mayor of Belfast, and the Rev. Dr. Hamilton, president of Queen's College, three papers were read. The first was by Mr. C. F. L. Giles, the engineer to the Belfast Harbour Commissioners, and gave a brief description of the harbour and its development. Mr. E. H. Tennyson D'Eyncourt followed with a paper "On Fast Coaling Ships for our Navy." The author proposed that certain vessels should be built specially to wait on the fleet and supply it with coal in time of war, and they should be fitted with appliances for transferring the fuel to the warships at sea. These vessels should be able to steam 17 knots easily and continuously, and 18 knots in case of emergency. They would have to be of considerable size, therefore, and would be loaded with 10,000 tons of coal, besides that needed for their own use. The author estimated that the requirements could be met on a length of 550 feet, a beam of 66 feet, and a draught of 27 feet with 10,000 tons of coal on board; that would enable the vessels to get through the Suez Canal. The horse-power necessary for 17 knots would be about 12,000. With quadruple engines the consumption of coal would be 1½lb. per I.H.P. per hour, so that at full speed the collier could go 1000 miles from the coaling station and back on 800 tons of coal, carrying 10,000 tons of coal for the use of the fleet. That would be sufficient to coal completely five of our largest battleships or cruisers, or, if needed, ten such battleships could have their bunkers half full.

Comparing this with the present conditions, it would take one of our large cruisers or ironclads four or five days to make the 2000 miles, and she would lose at least 1000 tons of coal, and have to be steaming hard all the time. The vessel would arrive with dirty boilers, a tired complement of stokers, and the greater part of her coal already burnt. In ordinary peace time the colliers could be used for taking coal to the coaling stations. The cost of these vessels, fully equipped, with Temperley transporters and all the necessaries for quick coaling, would be about 270,000*l*. each, so that four or five could be built for the cost of one first-class armour-clad or cruiser, whilst four could be kept in commission for about the cost of keeping up an armour-clad. In time of war, the author claimed, each collier would be equal to several additional warships, as it would enable so many of the latter to remain at sea, saving them the time of going to and fro for coal, and giving them an opportunity to clean their boilers and do minor repairs to the engines, besides resting the whole crew, officers and men. In the discussion which followed the reading of this paper, it was pointed out that it was more reasonable to transform a mercantile vessel into a collier in time of war than to build such vessels purposely for an occasion that might never arise.

Mr. James Hamilton, of Glasgow, next read a paper in which he described an ingenious means which he had devised for converting a moderate speed steamer into one of very high speed for war-like purposes. He pointed out that the extreme speed now demanded by the Admiralty for the new mercantile cruisers to which it was proposed to give subsidies was higher than could be used, with profit to the owners, during peace time for ordinary Transatlantic service. The Admiralty asked 25 knots; Mr. Hamilton put the limit for mercantile use at 22 knots. If engines are not worked up to the power for which they are designed, they are uneconomical in themselves, whilst for excessive speeds very great engine power is needed. In order to solve this difficulty, Mr. Hamilton proposes triple-screw steamers, with one central screw and two wing screws. For the 25-knot speed all three screws would be used, and their respective engines would therefore be at work at their full power, and so be operating economically; for the 22-knot speed the two wing screws only would be used, and in order to prevent the drag of the central, idle propeller, the latter is drawn forward, with its shaft, until the blades of the screw touch the stern-post of the ship. This stern-post is so formed that the blades lie snugly against it, and in this way the resistance of the water flowing past the idle propeller is got rid of. For a four-bladed screw the stern-post is made of cruciform shape by the addition of two horizontal wings. In the discussion on the paper, it was pointed out that the shape of the stern-post was not favourable to speed on account of the eddy-making resistance. Mr. Hamilton, in reply to the discussion, said, however, that the objection was not of so serious a nature as was supposed, supporting his contention by diagrams illustrating the stream-line theory.

On the second day of the meeting, Wednesday, June 24, Prof. J. H. Biles read a paper "On Cross-Channel Steamers," in the course of which he gave particulars of certain vessels, and discussed the different qualities needed

for success in this particular kind of craft. The paper was illustrated by a large number of drawings of various vessels.

A paper "On Registered Tonnages, and their Relation to Fiscal Charges and Design" was read by Mr. James Maxton. In this the author pointed out some of the absurdities and anomalies incidental to the present stage of the law in regard to the tonnage of ships. A long discussion followed, in the course of which many speakers gave expression to the opinion that a change in the law was absolutely necessary in the interests of shipowners, harbour authorities, and, also, passengers. Several shipowners who spoke laid it down as a principle that in cross-channel steamers every passenger should have a separate berth, and it was only the way in which tonnage was measured that prevented such a desirable feature being introduced.

Prof. W. H. Watkinson read a paper in which he described some new features of superheaters. He pointed out that, even with a separate condenser, and all the other improvements that have been made since the time of Watt, from 12 per cent. to 30 per cent. of the steam supplied to an engine is condensed during its admission to the cylinder. The steam turbine is the only engine in which this condensation of the steam by previously cooled surfaces does not take place, but the steam in turbines is wet from expansion while doing work. Liquefaction of steam may be reduced by steam jacketing; by compounding the cylinders; by steam separators; by a special arrangement for sweeping the condensed steam out of the cylinder at each stroke; by reduction of clearance surface; and by superheating. The last, the author said, was by far the most effective. During superheating, although the pressure of the steam remains constant, its volume is greatly increased. The amount of heat required to superheat 1lb. of steam by 150° F. is 72 British heat units; this is only about 6 per cent. of the heat required to generate 1lb. of dry saturated steam. The increase in volume due to this additional 6 per cent. of heat averages about 30 per cent. In some cases where superheated steam is used, the superheating is only carried so far as to reduce, or at most to annihilate, initial condensation. In these cases the steam, after it has been admitted to the cylinder of an engine, becomes ordinary saturated steam before or at cut-off, so that during expansion some condensation of steam takes place, due to work being done at the expense of the internal heat of the steam. There is, then, no advantage due to the increase of volume of the steam during superheating, but there is great saving in steam and in coal, due to the reduction of initial condensation and leakage of steam past the valves and pistons. In the case of large engines of the usual type, it is not possible to superheat the steam by more than 200° F., and in some cases there is trouble with the valves if the degree of superheat exceeds 150° F. With piston valves the limit can be considerably exceeded. The author next discussed the question of independently-fired superheaters, and those in which the apparatus is placed in the uptake of the boiler or is heated by gases from the furnace. A superheater to which a gas-producer was attached was also illustrated and described by the author.

In the discussion on this paper, Mr. A. F. Yarrow said that superheating was the direction in which engineers must look for improvement in the economy of the steam engine. The difficulty in lubricating the cylinders of steam engines had been spoken of, but it was well known amongst engineers that for years the torpedo boat builders had never used internal lubrication for the engines of the craft they built. It was interesting to note that water would ooze through places where steam would not pass, and for this reason piston valves might be worked with superheated steam without metal being in rubbing contact with metal. Mr. A. Morcom gave some particulars of a vertical engine in which superheated steam had been used. It was a 500kw. engine, and the steam was at 600° F. With saturated steam the consumption of water per kilowatt-hour was 21lb.; with superheated steam it was 16lb.

During the stay in Belfast, the shipyard and engine works of Messrs. Harland and Wolff, and those of Messrs. Workman and Clark, were visited. There was a steamer trip down Belfast Lough, a reception at the harbour offices, and a dinner given by the Right Hon. W. J. Pirrie at his residence at Ormiston.

On Thursday, June 25, members proceeded to Dublin, where they attended a garden party given by the Lord Lieutenant at the Vice-regal Lodge; rain entirely spoilt the pleasure of the reception. In the evening there was a ball at the Mansion House.

On the following day the members met in the lecture theatre of the Royal Dublin Society, when Mr. A. F. Yarrow, vice-president of the Institution, occupied the chair. A paper by the Hon. C. A. Parsons was first taken, the subject being "Modern Steam Turbines, and their Application to the Propulsion of Vessels." The paper was largely of an historical nature, and gave particulars of the various vessels in which the steam turbine had been fitted, such as the two unfortunate torpedo-boat destroyers, *Viper* and *Cobra*, which were both lost at sea. The *King Edward* and *Queen Alexandra* were two passenger steamers that had been running successfully on the Clyde. The *Queen* is a cross-channel steamer, built for the Dover-Calais route, and has been put on her station since the paper was read. She has machinery of 8000 I.H.P. On her trial on the Skelmorlie mile she made a mean speed of 21·73 knots. Another boat of the same type, to be fitted with turbine engines, has been built for the L.B. and S.C.R., and will be put on the Newhaven-Dieppe route. She is 280 feet long and of 34 feet beam, and will shortly be launched. Three large yachts have lately been fitted with steam turbines, the largest being the *Lorena*, built by Messrs. Ramage and Fergusson, of Leith. She is 253 feet in length and of 33 feet 3 inches beam. The steam turbines in this vessel are similar to those of the *King Edward* and *Queen Alexandra*, but somewhat larger. The trial of the *Lorena* took place in the Firth of Forth in May, the speed attained being 18 knots. The turbine yacht, the *Tarantula*, built for the late Colonel McCalmont by Messrs. Yarrow and Co., was of the torpedo-boat type, but with somewhat heavier scantlings. She made 25·36 knots on her trial trip, her displacement being 150 tons. The *Velox* is a torpedo-boat destroyer recently purchased by the British Admiralty. She has machinery similar to that which was in the *Viper*, and will be capable of developing upwards of 10,000 H.P. Two small triple-expansion reciprocating engines, each of 150 H.P., are fitted for cruising speeds up to 13 knots. The steam from these exhausts into the turbines, where its expansion is completed before it passes to the condensers. Another torpedo-boat destroyer, the *Eden*, will have machinery of 7000 H.P., and her speed will be 25½ knots; whilst a third-class cruiser, *Amethyst*, built for the British Government, will have turbines of 9800 I.H.P., her speed being 21¾ knots. The author looked forward to the time when steam turbines would be fitted to vessels of the largest size, such as Atlantic liners. The experience with the marine turbine up to 10,000 H.P. in ships of fast as well as of moderate speed had tended, he claimed, to justify the anticipation—guided by theory—that the larger the engines the more favourable would be the results as compared with the reciprocating engines. The saving in weight, space, attendance and power would be still more marked with turbine engines of above 10,000 H.P., and up to 60,000 H.P., for which designs had been prepared.

The remaining paper read at the meeting was on the Dublin Harbour works, the author being Mr. J. P. Griffith. During their stay in Dublin the visitors took a steamer trip down the Dublin Bay, and on the evening of Friday the Institution dinner brought the meeting to a close.

THE INTERNATIONAL CONGRESS FOR APPLIED CHEMISTRY.[1]

SO many papers on analytical methods were presented that it is impossible even to enumerate them. The International Commissions on Analysis and on the Analysis of Fodders and Manures had not received all the reports yet which the Paris meeting had called for; the two Commissions over which G. Lunge presided—Maercker (Halle), chairman of the second Commission, having died—held some of their meetings jointly with sections i. (analysis) and vii. (agricultural chemistry). The proposals for a uniform method of drawing up analytical reports were made by W. Fresenius (Wiesbaden); Ch. Guillaume (Sèvres) reported

[1] Continued from p. 158.

on the mass of the c.o. of water and on thermometer scales.

Section ii. received some important communications on the auto-purification of waters. G. Weigelt (Berlin) has experimented on the rates of diffusion of refuse waters into river courses when introduced in different circumstances; tests based upon average contamination are quite misleading when injury to the fish is concerned. River water can, owing to its contents in carbonates, bind enormous quantities of sulphuric acid and also of alkalis, by decomposition of the bicarbonates, and iron salts are quickly deposited. F. Fischer (Göttingen) spoke on technically pure water, and regretted that biological tests seemed to supplant chemical analysis; the methods of sample taking were faulty. In section viii. Vandevelde (Gand) remarked that rest, absence of antiseptic and chemical compounds, presence of living organisms, and aëration favoured the auto-purification of water courses. Hygiene and navigation were in opposition; in flat country districts rivers should be doubled, a canal to serve for navigation, and the old bed for purification. Ch. Dreyfuss spoke on the septic tanks of Manchester, Proskauer and Erlwein on the ozone-sterilisation plants of Siemens and Halske at Wiesbaden and Paderborn. On the suggestion of Klaudy (Vienna) it was resolved to bring the water question before the next congress.

G. Lunge reviewed the state of the sulphuric acid manufacture in a very able paper, recommending water-sprays (not vapour) for the lead chambers, and reaction plate towers with artificial draught, and pointing to the great improvements lately effected in concentration apparatus. Kestner (Lille) described his lead ventilators for artificial draught. E. Hart (Easton, Pa.) reported on sulphuric acid in the United States since 1900, and D. Pennock (Syracuse, N.Y.) on the progress in the soda industry in the United States. G. Beilby (Glasgow) reviewed the position of the cyanide industry, pointing out that the actual plants could supply more than twice as much cyanide as is wanted. Synthetic cyanide processes were further discussed, in different sections, by F. Rössler, G. Erlwein, and A. Frank. The latter two spoke particularly on the Caro-Frank process taken up by Siemens and Halske. The carbides of barium and calcium bind nitrogen when powdered and heated, forming $CaCN_2$, which, on extraction with water, yields $(CN.NH_2)_2$, and on fusion with salt (soda was used for the barium compound which was first prepared) sodium cyanide. The calcium cyanamide can also directly be prepared in the electric furnace from lime, coal, and atmospheric nitrogen. Decomposed with water vapour under pressure ammonia results; the calcium cyanamide also gives off ammonia in the soil, and is used as manure under the name of Kalkstickstoff. J. Bueb (Dessau) explained the recovery of the cyanogen from illuminating gas.

F. Mylius (Reichsanstalt) showed that the loss of weight which glass undergoes when treated with water would afford a basis for the classification of chemical glasses; an electric conductivity test practically gives the necessary data. R. Dralle described glass blowing machines; Heinecke, recent improvements in keramics effected at the Royal Porcelain Manufactory of Berlin; Vogt (Sèvres) and Heintze (Meissen) also contributed communications on their porcelains. H. Heraeus, of Hanau, showed his new resistance furnaces, in which platinum foil 0.007mm. in thickness is used instead of wire. The new iridium furnace, also shown, is an iridium tube 0.3mm. in thickness, which was directly heated by continuous currents up to 2000° C. With the aid of these furnaces and the experienced glass-blowers of Siebert and Kühn, of Cassel, quartz vessels are now made in Hanau. Ordinary quartz crucibles cost about half as much as platinum crucibles; they are attacked by metallic oxides and are permeable to hydrogen above 1300° C. (1100° C. according to Hahn), but do not crack on sudden cooling; water gas converts the quartz into tridymite. Siebert and Kühn had quartz thermometers on view. W. Hempel (Dresden) constructs simple high temperature furnaces by cementing small carbon rods to a zig-zag surrounding the crucible; the shell is iron lined with kieselguhr and carbon. Using an arc furnace and placing the substance in the cup of a hollow carbon rod, he has determined the following melting points:—magnesia, 2250°; lime, 1900°; alumina, 2068°; magnesite, 2000°; porcelain (Berlin) softens at 1550°; Meissen porcelain at 1850°. In these experiments a rod rests loosely on the substance, and breaks a contact when sinking. The temperature is determined with a Holborn-Kurlbaum optical pyrometer, or a Bunsen photometer of Hempel's, in which the rays are several times reflected: for this reason Hempel himself regards all these preliminary values as probably too low. H. Bunte (Karlsruhe) demonstrated with the aid of laboratory mantles that neither pure thoria nor pure ceria yield the high luminescence which we obtain by mixtures, and that very small percentages of uranium, platinum, &c., in thoria also produce brilliant lamps, but that none of these are durable. The luminosity is probably simply physical, but there may be catalysis.

Section iii*a*., metallurgy, discussed papers by H. Wedding and Th. Fischer on metallic hydrides, by C. Schiffner (Freiberg) and A. Lodin (Paris) on pyritic smelting, by Ch. E. Munroe (Washington) on mining, metallurgy, and explosives in the United States, Gin (Paris), on extraction of copper pyrites with SO_2, &c. In section iii*b*. Brunswig, Bichel, Blochmann, Mettegang, Eschweiler, Watteyne, O. Guttmann (London), Knight (Krümel), Lenze, Bergmann and others had long discussions on the Trauzl lead block test, determination of explosive velocities, transport of compressed gases and liquids, protection of explosive works against lightning, danger from perchlorates in powder, &c. O. Guttmann's proposal for an international committee on explosion tests in experimental mine galleries did not find sufficient support.

Section iv*a*. had many good papers by C. Engler, Bergner (Baku), Aisinmann (Campina), E. O'Neill (California), Harperath (Argentina) on petroleum; Charitchkow (Grossny) proposed to fractionate technically naphtha in the cold by means of alcohol mixtures. Connstein (Berlin) described the successful splitting-up of fats by the enzymes contained in Rhicinus seeds, &c.; Lewkowitch (London) referred to the same subject. Other papers were on cyanogen, illuminating and water gas (Bunte and F Fischer), saccharin (Fahlberg), &c.

Sections iv*b*., dyes; v., sugar; vi., fermentation and starch; vii., agricultural chemistry; viii., hygiene, pharmaceutical and medicinal chemistry, and foods; xi., legal and economical questions, were all very busy.

Section ix., photochemistry, discussed papers by J. M. Eder (Vienna) and Ollendorf (Berlin) on sensitometers; on latent images, by J. Waterhouse (Eltham) and Schaum (Marburg); on colour photography by additive synthesis, by A. Miethe and R. Neuhaus (Berlin); on photochemistry in the United States, the centrifugal bromide of silver, and other points, by L. Baekeland, Yonkers, N.Y.; on the resolution of the finest spectrum lines on Doppler's principle, by O. Lummer; and an exhaustive study of the dichroic fog, by A. Seyewitz (Lyon).

In section x., electrochemistry and physical chemistry, J. Traube and G. Teichner (Berlin) performed an experiment apparently disproving Andrews's views on the critical state of gases. A glass tube is partly filled with carbon tetrachloride; it contains also little spherical floats of glass of different densities. The tube is jacketed with paraffin and diphenylamine. When heated to and above the critical point, the meniscus disappears, and the floats do not all collect in the middle portion of the tube. This is to prove that there is no uniform density in the vapour. Repeating experiments of de Heen and Dwelshauvers-Dery, Traube considers that van der Waals's molecular gas volume constant b is not constant, but increases when the liquid passes into the gaseous state, and that the vapour contains liquidogenous and gasogenous molecules the proportions of which depend upon the temperature. At the critical temperature both molecules are soluble in one another in any proportions.

W. Nernst (Göttingen) showed an apparatus with the aid of which he has determined the vapour densities of CO_2 with 0.3017mg., of NaCl with 0.16mg., of S with 0.57mg. of substance. The substance is brought in an iridium vessel, which is lowered into a tubular iridium furnace of Heraeus and heated up to 1950° C. The weighing is done on a balance, consisting of a capillary glass tube as beam, bent down at the end to serve as pointer, and resting on a quartz thread; this balance weighs to 0.001mg., and can be loaded with 2mg. maximum. The values found

are, *e.g.* H_2O 17·1 (instead of 18), CO_2 42·9 (44), S 36 and 37·7 (32), so that the sulphur would appear to be monatomic at that high temperature.

E. Wedekind (Tübingen) produces colloid zirconium by reducing the oxide with magnesium and extracting with hydrochloric acid; O. Burns (Boston) colloids of paper, oxides, sulphides, &c., by shaking them for many hours. Monti (Turin) spoke on the concentration of solutions, perfumes, wines, and ordinary salts by freezing; the acids and salts collect in the microscopical interstices between the small ice crystals, and when frozen blocks are left to themselves, the substances diffuse downward; concentration by cold is more economical than by heat. Bredig (Heidelberg) and Count Schwerin (Höchst) spoke on electric osmosis, E. Solvay (Brussels) on a gravitation formula applicable to diffusion phenomena, Zengelis (Athens) on the production of very high temperatures by burning aluminium in oxygen and other gases. The kinetics of the catalytic sulphuric acid process were discussed by Knietsch (who has worked the process out in Ludwigshafen) in section ii., and by Bodenstein and Bodländer in x. Similar papers were read by Schenck (Marburg) on the splitting of CO, by H. Goldschmidt (Christiania) on the kinetics of reductions, by Bodländer on technical catalysis. H. Goldschmidt (Essen) reported on the manufacture of steel in the electric furnaces of Stassano, Gin-Leleux, Héroult, Keller, Kjellin, and others; Bancroft and A. A. Noyes on electrochemical research in the United States; Fr. Foerster (Dresden) and Brandeis (Aussig) on electrolytic preparation of inorganic compounds; M. Le Blanc (Karlsruhe) spoke on electrolysis with alternating currents and the possibility of determining the velocity of ionic reactions; Coehn (Göttingen) on electrode influence in electrolytic oxidations and reductions, H. Moissan on metallic carbides, Héroult on the efficiency of electrolytic soda processes, Danneel and Nissenson on the electrolytic deposition of metals, Küster (Clausthal) on dissociation pressure of soda solutions, W. Marckwald on his radio-active tellurium, and Precht (Hanover) on the spectrum and atomic weight of radium (in ix.). W. von Bolton demonstrated what he briefly calls luminosity of the ions. When a carbon rod is lowered as anode into sulphuric acid, containing a copper spiral as kathode, the rough surface of the carbon becomes at once bright under the influence of currents of 110 volts. When rods of metals (or of carbon) are dipped into solutions of their salts, the rod being the kathode, a platinum spiral the anode, the rod begins to glow in brilliant colours, and beautiful band spectra of the ions (?) are obtained, differing from the spark spectra which result when the anode is glowing. The discussions were very good.

H. BORNS.

SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THE eighth annual congress of the South-Eastern Union of Scientific Societies was held at Dover on June 11–13. A lively address by the president, Sir Henry Howorth, F.R.S., put pin pricks into all the infallibilities, begging the student to accept no predominant hypothesis without demur, to resist the fascination of great names, to challenge the exactness even of the exact sciences. Fallacies might often lurk in phrases, as when "the survival of the fittest" was glibly used to mean nothing more than the survival of the survivors. The address impressed its hearers with the advantage which every branch of science might derive from the touch of a keen and active critical faculty, working outside the ranks of the specialists.

The papers contributed to the congress fall into three classes, the purely local, the general, and those of divided interest. In the last of these Mr. A. T. Walmisley's essay discussed the methods by which a traveller between Kent and the Pas de Calais might cross the intervening strip of shallow water, on, in, under, or over it, without the incidents which now so often befall him when the "silver streak" is converted into a tumultuous concourse of atoms. The new turbine steamer was indicated as the best chance for humanity—at least until something better is invented. Mr. W. Whitaker, F.R.S., observed that clearly nature had expressly designed the Straits of Dover for a submarine tunnel, though politicians might think otherwise. Mr. A. O. Walker, dealing with the effects of climate on distribution, compared his long experience of the fauna and flora of Cheshire and North Wales with his later observations while residing near Maidstone.

Of local papers the most important was that by Mr. Sydney Webb and Captain McDakin on the disappearing fauna and flora of the district. There were many lamentable and in part unavoidable losses. The dwindling of the colony of seals at Beachy Head was deplored, but no tears were seen to fall at the news that vipers were becoming scarce and polecats scarcer. The congress museum was instructively adorned by Mr. Webb's fine collection of Lepidoptera with their caterpillars, and by the display of plants with their seedlings from the Catford Society.

Prof. Boulger opened a discussion on the best means of checking the extermination of British plants and animals. Dr. Rowe, in a paper on the importance of zonal distribution, alluded to the doctrine that the souls of good geologists go hereafter to their favourite "sections," and hoped he might be allowed to stake out his claim to a particular slice of Dover Chalk, from which he had already abstracted about 5000 fossils.

The non-local discourses included an interesting account by the Rev. R. A. Bullen of "a late Celtic cemetery at Harlyn Bay," and a valuable investigation by Miss Ethel Sargent, who unfolded the story of Geophilous plants, explaining how these "lovers of the soil," to suit seasons and climates, for periods of varying duration, keep themselves close within the protecting bosom of their mother earth, the seeds and bulbs in the meantime, with a kind of vegetable instinct, ever using their foodstore to the best advantage. The concluding address was by Dr. Jonathan Hutchinson, F.R.S., the retiring president, who at two successive congresses has delighted his audience by a finely-argued discussion of a subject not at the first blush very attractive. His theme was leprosy. His theory is now well known, that this disease is caused by the consumption of badly cured fish, or occasionally by the eating of food which has been handled by lepers. During the last two years he has visited Africa and India, everywhere seeking out lepers and leprous communities, especially in places where he had been told that a fish diet was out of the question. Everywhere he found that in that particular his informants had been misinformed. A quotation from Erasmus sent to Dr. Hutchinson by a classical friend represented the Pope himself as proposing to proscribe the use of salt fish on account of its supposed tendency to spread leprosy, though it is not salt fish in itself that lies under any evil imputation. Erasmus often makes ironical statements, but on the foul effects produced in his day by the consumption of putrid fish his dialogue "Ichthyophagia" speaks with no ambiguity.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speeches delivered by Prof. Love in presenting M. Poincaré and Prof. Story-Maskelyne for the honorary degree of D.Sc. at the Encænia on June 24:—

Nescio an maximus inter mathematicos qui nunc vivunt sit Henricus Poincaré: vir iure mirandus non solum quod novis viis quærendi usus novos fructus adeptus est, sed quod tot et tam diversa doctrinæ genera unus complecti potuit, cum commentariis innumerabilibus fere omnes geometrices et analyseos partes illustraret. Cum in hæc recondita doctrinæ arcana altius penetrasset, rite eum Regalis Societas ornavit numismate aureo in memoriam Professoris nostri Sylvester instituto quod ei primo datum est. Non solum subtilissimis illis quæstionibus quæ de mathematicæ veritatis natura inter philosophos oriuntur hunc auctorem plerique sequuntur, sed ingenii maximi viribus nisus de luce, de vi electrica, de difficillimo quoque doctrinæ genere præclarissime disseruit. In Astronomia certe ea de motu et de figura planetarum est commentatus ut omnibus de hac re quærentibus nova quadam et meliore via insistendum sit. Hunc talem virum in omni genere doctrinæ insignissimum, rerum naturam animo peragrantem, geometren, physicum, astronomum præstantissimum, Academia nostra inter suos doctores libentissime adscribit.

Septem et quadraginta abhinc annos Willelmo Buckland successit Mervin Herbertus Nevil Story-Maskelyne, Minera-

logiæ primo Prælector mox Professor factus, quem honorem, nulli antea apud nos concessum, novem et triginta annos nullo intervallo retinuit, nec nisi octo abhinc annos deposuit. Primus etiam eodem fere tempore minerarum in Musæo Britannico custos creatus trium et viginti annorum labore effecit ut maxima vis minerarum omnium, nusquam alias in omni orbe terræ invenienda, intra parietes Musæi Britannici congereretur. Quod ad scientiam exquisitiorem pertinet, natura lapidum de cælo iactorum investiganda summam laudem adeptus est: idem minerarum et crystallorum formas et species accuratissime descripsit. Sed magistri boni præcipua laus in discipulis constat, neque silendum arbitror multos ex iis, qui hodie in hac scientia principes et signiferi sunt, hoc auctore et Professore doctissimo usos esse. Idem rude iam donatus a Musæo Britannico ita recessit ut rei publicæ se daret et Crickladensium suffragiis ornatus in publico totius civitatis consilio indivisi imperii vindex et defensor acerrimus sederet. Addo quod Regalis Societatis Sodalis et Collegii Wadhamensis socius honoris causa creatus cum multis virorum doctorum societatibus et in Europa et in America litterarum commercio coniunctus est.

PROF. J. LARMOR, F.R.S., has had the honorary degree of doctor of science conferred upon him by the University of Dublin.

A COMMITTEE has been formed with the object of raising a memorial in honour of the late Mr. T. G. Rooper, who died on May 20. Mr. Rooper held the office of H.M. Inspector of Schools in the Isle of Wight, Southampton and the neighbourhood during the last seven years, and both in his district and elsewhere he promoted the development of rational teaching of geography, natural history and other science studies. Information concerning the proposed memorial will be gladly supplied by Profs. F. J. C. Hearnshaw and J. F. Hudson, Hartley University College, Southampton.

THE appeal for funds for extending and modernising the scientific departments of the University of Dublin, to which reference was made last week (p. 188), should receive liberal support not only from graduates of the university, but also from all who sympathise with the cause of higher education in Ireland. Each science department of the university is in need of funds for laboratories, instruments, and other means of study and research. The university has already made considerable outlay in order to increase the efficiency of the scientific departments, but the new demands created by modern developments are too many and extensive to be met by existing resources, and it is necessary to ask for additional endowments if the university is to maintain its high position among the educational forces of the British Isles. In making the appeal for funds, it is pointed out that the important position assumed by modern science as a subject of collegiate education, and the great expansion of the scientific professions, render it incumbent on the older universities to make a costly provision for the adequate teaching of the experimental sciences. Not only must the universities of to-day be able to extend to their students—whether professional or in arts—sound theoretical and practical instruction in the established principles of science, but if these corporations are to continue to fulfil their duties efficiently, they must, in addition, provide facilities for research available both to student and teacher. In short, the demands on the resources of universities are not only for the endowment of chairs of science and the salaries of assistants and demonstrators, but also for the provision, equipment, and maintenance of lecture-rooms for teaching, and laboratories for both class-work and research. Moreover, the provision for laboratory equipment must be adequate to meet the ever-fresh demands of scientific advance. In the past the University of Dublin has discharged her duties towards the newer studies in a manner which has, in many particulars, set example to wealthier bodies. But a time has arrived when expenses must be incurred beyond her existing resources, and the University of Dublin must either obtain external aid to build and equip laboratories and lecture-rooms for physical science, electrical and mechanical engineering, botany and zoology, or conduct under grave disadvantages the instruction of those students who require to include these subjects in their professional training, or in their courses in arts.

A REPORT drawn up by a committee appointed by the Board of Trinity College, to consider the present scientific requirements of the college, shows that a sum of at least 100,000*l.* is needed by the scientific schools of the university. The appeal from which this statement of position and needs of the university has been taken is signed by Lord Rosse (Chancellor of the university), Mr. D. H. Madden (Vice-Chancellor of the university), Prof. Geo. Salmon (Provost of Trinity College), Lord Ashbourne, Lord Lansdowne, Lord Pembroke, Lord Ardilaun, Lord Iveagh, Lord Rathmore, Mr. E. H. Carson, Mr. W. E. H. Lecky, and Mr. J. H. M. Campbell. To carry the recommendations of the committee into effect, a considerable expenditure (for which no provision can be made out of college funds) must be incurred, including a capital outlay (for building and fitting laboratories and the like purposes) of 34,000*l.*, in addition to an annual charge for increased salaries and other expenses, estimated at 2730*l.* per annum. Lord Iveagh has generously offered to provide the capital sum of 34,000*l.* so soon as a sufficient amount has been collected and invested to produce the annual outlay contemplated by the committee (viz. 2730*l.* per annum), and this offer will hold good for three years from May 1 next; or if a sufficient annual income is assured by investments for carrying out the recommendations of the committee for any one department, he is prepared to contribute the capital expenditure necessary for the equipment of that particular department. A very large sum has to be collected during the next three years, but Lord Iveagh's offer ought to inspire others to contribute as generously as they are able to the subscription list. The Chancellor of the university, Mr. Benjamin Williamson, and Prof. W. E. Thrift are acting as honorary treasurers of the science fund.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 14.—"On the Radiation of Helium and Mercury in a Magnetic Field." By Prof. Andrew **Gray,** F.R.S., and Walter **Stewart,** D.Sc., with Robert A. **Houstoun,** M.A., and D. B. **McQuistan,** M.A., Research Students in the University of Glasgow.

The experiments had for their object primarily to test for lines of different substances, the proportionality of the change $d\lambda$ of wave-length, for each of the components into which a single spectral line is resolved by the application of a magnetic field, to the field intensity H, and to deduce the corresponding values of the ratio e/m of charge to mass of the electron. The apparatus consisted of a set composed of a large electromagnet (built to Prof. Gray's specification), and an echelon spectroscope of twenty-six plates with auxiliary (by Hilger, London). The readings were obtained by means of a micrometer eye-piece fitted to the observing telescope. The first observations were made at right angles to the magnetic field on several of the helium lines, and on the green line of mercury. The results were used to calculate the values of $d\lambda/H\lambda^2$, and of e/m by the formula $e/m=2\pi v.d\lambda/H\lambda^2$, where v is the velocity of light, 3×10^{10} cm. per second. In every case the normal triplet was obtained, and the separation between the extreme components found to be proportional to H up to fields of 10,000 C.G.S.; at fields above this the light becomes so faint, in all the tubes with which the authors worked, that it is impossible to obtain readings. The following table shows the results:—

Substance.	Wave-length, 10^{-8} cm.	$d\lambda/H$.	$d\lambda/H\lambda^2$.	e/m.
Helium ...	5016 (green)	$1{\cdot}61\times10^{-5}$	$6{\cdot}41\times10^{-5}$	$12{\cdot}1\times10^6$
,,	5876 (yellow)	$2{\cdot}07\times10^{-5}$	$6{\cdot}00\times10^{-5}$	$11{\cdot}3\times10^6$
,,	6678 (red)	$2{\cdot}90\times10^{-5}$	$6{\cdot}49\times10^{-5}$	$12{\cdot}2\times10^6$
Mercury...	5461 (green)	$2{\cdot}12\times10^{-5}$	$7{\cdot}12\times10^{-5}$	$13{\cdot}4\times10^6$

At a field intensity of 13,000 C.G.S. the centre component of the normal triplet was doubled, while each of the outer components was itself tripled. The polarisation of the two triplets and of the central doublet was the same

as that of the lines from which they originated, namely, that of the lines of the normal triplet. At all fields up to 13,000 the faint companion to the yellow helium line D_3 was not tripled, but only doubled.

For the above lines observations were made also along the lines of force, one of the magnet cores being replaced by a core drilled from end to end with a hole about a centimetre in diameter. The following table gives the numbers obtained :—

Substance.	Wave-length, 10^{-8} cm.	$d\lambda/H$.	$d\lambda/H\lambda^2$.	e/m.
Helium .	5016	1.75×10^{-5}	6.95×10^{-5}	13.1×10^6

Mercury...	5461	1.88×10^{-5}	6.31×10^{-5}	12.0×10^6

With respect to the green mercury line of wave-length 5461 tenth-metres, the authors incidentally observed fully a year ago, as they found afterwards had also been done a little earlier by Zeeman, that the line appeared to have three faint companions on the violet side, and two (they seemed at times to see three) on the red side. The companions are visible only under special conditions of the discharge tube. The values of $d\lambda$ for the first three are -0.208, -0.096, -0.059, and for the other two $+0.032$, $+0.067$. Though those values do not in every case agree with those given by Perot and Fabry, it is possible that, on account of hitherto unexpected complexity of the line, both sets of observations are correct.

It ought to be noticed here that Runge and Paschen have obtained a resolution of the green mercury line into three triplets in the magnetic field. This observation is entirely confirmed as to the side triplets by those of the authors (which were made before Messrs. Runge and Paschen's paper came to hand), but they have not been able to verify Runge and Paschen's result for the middle group, which appears to the authors to be a doublet. But the instrument of Runge and Paschen was a large Rowland grating of 6.5 metres diameter of circle, and the spectrum was photographed, so that their observations were, no doubt, more certain than the authors'.

May 28.—"Note on the Effect of Extreme Cold on the Emanations of Radium." By Sir William **Crookes**, F.R.S., and Prof. James **Dewar**, F.R.S.

The first endeavour was to ascertain whether the scintillations produced by radium on a sensitive blende screen were affected by cold.

A small screen of blende with a morsel of radium salt close in front was sealed in a glass tube, and a lens was adjusted in front so that the scintillations could be seen. On dipping the whole into liquid air they grew fainter and soon stopped altogether. Some doubt was felt whether this might not have been caused (1) by the presence of liquid, (2) by the screen losing sensitiveness, or (3) by the radium ceasing to emit the heavy positive ions. To test this two tubes were made, in one of which the radium salt could be cooled without the screen, and in the other the screen could be cooled while the radium salt was at the ordinary temperature.

The results were as follows :—(1) Radium salt cooled by liquid air. Screen at ordinary temperature. Scintillations quite as vigorous as with radium at the ordinary temperature, the screen and radium being *in vacuo*. (2) Radium at the ordinary temperature and screen cooled in liquid air. As the screen cooled the scintillations became fainter and at last could not be seen. On allowing the temperature to rise the scintillations recommenced. (3) A screen with a speck of radium salt in front of it was sealed in a tube. The tube was sealed off when a few fine drops of water were still remaining in the tube. The scintillations were well seen in this saturated aqueous vapour. The lower end of the tube was dipped in liquid air, which instantly condensed the aqueous vapour and left a very good vacuum. On now examining the scintillations they were if anything brighter and more vigorous than at first. When liquid hydrogen cooling was used instead of liquid air, the action was equally marked, showing that the highest vacuum that can be obtained by the action of cold does not diminish the scintillations.

In order to test the activity of radium in rendering air electrically conductive some radium bromide was sealed up in a glass tube and heated to the highest temperature the glass would stand, during the production of as high a vacuum as the mercurial pump would give. The whole tube was then immersed in liquid hydrogen contained in a vacuum vessel. On bringing the radium in such a vessel into a room in which a charged electroscope was placed it began to leak when the tube of radium surrounded with liquid hydrogen was some three feet away, and was very rapid in its action when a foot away from the electrometer. On immersing the tube containing the liquid hydrogen with submerged radium in another large vessel of liquid air and bringing the combination near the electroscope, the action was the same.

Prof. Rutherford and Mr. Soddy have made the important discovery that a condensable emanation is diffused into gases from solutions of radium salts, which is capable of condensation from the gas mixture at the temperature of liquid air. As it was important to ascertain what was taking place in this respect with the anhydrous radium bromide when isolated in the highest vacuum, the following experiment was arranged :—A glass apparatus was constructed consisting of a ∩-shaped tube having a bulb at one end, and being drawn out to a capillary tube at the other. Above the bulb was a plug of hard-pressed purified asbestos. The radium salt was located at the bottom of the bulb, and the whole was most carefully heated, exhausted to the limit of the mercurial pump, and sealed off. In the dark no trace of phosphorescence could be seen in any part of the apparatus unless from the pieces of the radium bromide. The capillary tube was now immersed in liquid air in a large flask, so that distillation might proceed undisturbed for days. After twenty-four hours of this operation, on looking at the capillary tube while covered with the liquid air, a marked phosphorescence was recognisable owing to some condensed emanation. The luminosity became naturally more marked the longer the time the action was allowed to proceed, and it is the authors' intention to continue the experiments for a lengthened period of time, and then seal off the fine capillary part so that the condensed product may be thoroughly examined.

Entomological Society, June 3.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. G. C. **Champion** exhibited numerous specimens of *Coccinella distincta*, taken in the pine woods of Woking. They were found, as usual, running about the ground in company with *Formica rufa*, and were perhaps wanderers from some other locality. Mr. Donisthorpe said the species was still common at Weybridge in the nests of *Formica rufa*, and that he had observed it also at Bexhill, while Mr. Chitty noted its former occurrence in Blean Woods in great numbers.—Mr. H. St. J. **Donisthorpe** exhibited a very remarkable melanic form of *Halyzia 18-guttata*, L., black with white spots, the type, which was also exhibited, being light brown with white spots. The former was taken at Oxshott on May 22. He also exhibited *Stilicus fragilis*, Gr., a melanic form with a black thorax instead of red as in the type, taken at Shirley on May 15; and *Staphylinus fulvipes*, Scop., taken by himself at Bamber Forest on June 1, a new locality for this rare beetle.—Dr. T. A. **Chapman** exhibited two full-grown larvæ of *Thestor ballus*, sent by Mr. H. Powell, from Hyeres, and read a description of them in their various stages. He also exhibited a larva of *Heterogyna paradoxa*, full fed, reared from the egg at Reigate, and a cocoon of *Orgyia auro-limbata*, with parasite microgaster. The microgaster and the moth both came from the same larva, and the moth, though containing a few eggs, laid none. An imago and a parasite from the same larva have not infrequently been recorded, but there has been some doubt on the occurrence.—The **President** exhibited the dry form of *Precis actia* bred by Mr. Guy A. K. Marshall from an egg laid by a female of the wet form. The parent was captured by Mr. Marshall at Salisbury, Mashonaland (5000 feet), on February 14; the egg was laid on the following day. It hatched February 20, the larva pupated March 16, the perfect insect, a male, emerged March 28. The differences between these two forms are as astonishing as those between the two phases of *Precis antilope* bred, the dry from the wet, by Mr. Marshall last year. The president said this

was the third South African species of the genus Precis in which Mr. Marshall had produced incontrovertible evidence of the specific identity of forms widely separated in colours, patterns, shape, relation of upper- to under-side, &c., and even instinct, including the selection of a particular type of country. The president also showed a small series of ants, part of a much larger collection made by the late W. J. Burchell in Brazil between the years 1825 and 1830. Considering their great age, the specimens were wonderfully well preserved, and were accompanied by remarkably exact and detailed data, and, in many cases, interesting notes on habits, instincts, &c.—Mr. O. E. **Janson** communicated a paper on the genus Theodosia and other Eastern Goliathides, with descriptions of some new species.—Colonel C. **Swinhoe** communicated a paper on new genera and species of the family Lymantriidæ in the National Collection.—Mr. G. W. **Kirkaldy** communicated a memoir on the Rhynchota collected by Dr. Arthur Willey chiefly in Berara and Lifu.—Prof. E. B. **Poulton** gave an account of experiments in 1893, 1894, and 1896 on the colour relation between certain lepidopterous larvæ and their surroundings, and especially the effect of lichen-covered bark upon *Odontopera bidentata* and *Gastropacha quercifolia*.

Mineralogical Society, June 9.—Dr. Hugo Müller, president, in the chair.—Mr. H. F. **Collins** gave an account of a remarkable mass of wollastonite with associated minerals which occurs at Santa Fé, State of Chiapas, Mexico. This mass of nearly pure wollastonite covers an area of 400 yards by 160 yards, and reaches to a depth of more than 300 feet; it is surrounded on all sides by granite, felsite, and other igneous rocks, and is separated by a mile from the nearest limestone. Near the outskirts of the mass occur extremely large crystals of wollastonite, most of which have been partially or entirely converted into quartz or semi-opal. Here are also found masses of garnet and of workable copper ores containing gold and silver. The author exhibited and described specimens of wollastonite, bornite in wollastonite, bornite in calcedony, gold-bearing linnæite, idocrase rock, and a remarkable intergrowth of bornite and galena resembling graphic granite.—Prof. H. A. **Miers** described the results he has obtained from the observation of the growth of crystals by a new method. The method consists in tracing the changes of angle upon a crystal during its growth by measuring it at intervals by means of a specially devised inverted goniometer, without moving it from the solution in which it is growing. It was found that an octahedron of alum yielded invariably three images for each face, so that the crystal had really the form of a very flat triakis-octahedron. Similar observations on other crystals lead to the conclusion that the faces of a crystal are in general not faces with simple indices, but vicinal planes slightly inclined to them, which change their inclination during the growth of the crystal. By determinations of the refractive index of the solution by means of total reflection within the crystal, it was found that in each case the liquid in contact with the growing crystal is slightly supersaturated.

Mathematical Society, June 11.—Prof. H. Lamb, president, in the chair.—The president announced that, after the conclusion of the current volume, some changes would be made in the form of publication of the *Proceedings*, the chief being an increase in the size of page and type.—The following papers were communicated:—Major P. A. **MacMahon,** The application of quaternions to the algebra of invariants.—Mr. G. B. **Mathews,** Jacobi's construction for quadric surfaces.—Mr. H. W. **Richmond,** Automorphic functions in relation to the general theory of algebraic curves. The object of the paper is to extend to curves in space of three or more dimensions the methods which have been developed by Poincaré and Humbert for the parametric representation of plane curves by means of automorphic functions. Curves are classified by their genus (or deficiency), their order and the number of dimensions of the space in which they lie, and the properties of all the curves in a class can be inferred from those of particular members of the class. The genera 1, 2, 3, 4, 5 are discussed in detail.—Prof. L. E. **Dickson,** Addition to the paper on four known simple groups of order 25920.—Prof. A. C. **Dixon** made an informal communication On a method of introducing the logarithmic function by means of geometrical properties of conics.

EDINBURGH.

Royal Society, June 1.—Dr. Munro in the chair.—Mr. George **Muirhead,** commissioner for the Duke of Richmond and Gordon, read a paper on the effect of temperature on the taking of salmon by rod and fly on the River Spey at Gordon Castle. From a careful examination of the full statistics which had been kept for a number of years, and a discussion of them in the light of various possible meteorological and climatic causes, the conclusion come to was that the number of salmon caught on a day was determined, to a large extent, by the variation of temperature during that day, the greater the variation of temperature the smaller the catch.—Dr. W. **Peddie** read a paper on the theory of colour vision. The theories which give the best account of the facts of colour vision and colour blindness are the Young-Helmholtz theory and Hering's theory. Both are trichromatic theories, and, apart from physiological or anatomical questions, both can, by proper choice of fundamentals, be made to give a good account of the main facts. The facts of one-eyed colour blindness show that, on the Young-Helmholtz theory, colour blindness must be regarded as due to fusion of at least two fundamental sensations. But the curves of one sensation, determined by observations on different eyes, differ considerably among themselves. This indicates that a broader basis for the theory may be desirable. This may be sought for in a tetrachromatic theory. But any such theory must explain the possibility of trichromatic representation of all colours. The theory proposed assumes two pairs of complementary stimulations, say, R, G_1 and G_2, V. In this respect it has a resemblance to Hering's theory. But whereas, in Hering's theory, stimulation of one member of a complementary pair means no stimulation of the other member, in the proposed theory equal stimulations of two such members gives white. It is shown that four sets of equivalent trichromatic fundamentals must exist. Assuming Helmholtz's fundamentals as such a set, the four mathematically possible sets of tetrachromatic equivalents, of which only one can exist physically, are deduced; and it is found that one of these does suit the known facts of colour vision and colour blindness. Choosing this set, the other three trichromatic equivalent sets (Helmholtz's being the fourth) can be deduced. The perceptibility curves (ordinates being differences of wave-length just appreciable to the eye in the spectrum) found for one of these sets is compared with that given by Helmholtz's set. The comparison is found to be very satisfactory. The nature of the tetrachromatic set shows that colour blindness must be regarded as due to suppression of one complementary pair of sensations, while variations in normal eyes are due to partial suppression. In this way the sensation curves for different eyes may have greater fixity as regards form, depending on wave-length, than in the trichromatic set. This result is desirable if the sensation curves are to be regarded as really corresponding to physiological stimulation produced photochemically or photoelectrically. A simple theory of such stimulation is given and shown to lead to the required form of relation between the four fundamentals.

June 15.—The Hon. Lord M'Laren in the chair.—Dr. **Horne** and Dr. **Peach** read a paper on the Canonbie Coalfield: its geological structure, &c. Though of limited extent, this coalfield has aroused considerable interest owing to the important series of plants obtained from the beds and to the questions bearing on the correlation of the Carboniferous rocks of the Scottish border with those of the north of England and centre of Scotland. About twenty years ago it was assigned by the Geological Survey to the Calciferous Sandstone series. At that time, however, great difficulty was felt in correlating the subdivisions of the Carboniferous rocks as there developed with those in the midland valley of Scotland, owing to the marked variation in some of the groups from the normal Scottish types. The palæontological evidence then obtained was not in accord with these conclusions, for the plants seemed to show that the coalfield really belonged to the true Coal-measures. Last year the Canonbie area was reexamined by the Geological Survey and Mr. Kidston. Deep bores have been sunk in recent years by His Grace the Duke of Buccleuch, and these also have furnished important geological evidence. By means of horizontal sections it was shown that the

following order of succession prevailed in the Lower Carboniferous rocks of that region:—(1) at the base, the Whita Sandstone resting on the Birrenswark volcanic platform; (2) the cement stone group; (3) the Fell Sandstones; (4) the Glencartholm volcanic group with Scorpion Bed; (5) a group of marine limestones, sandstones, and shales, with coal seams on two horizons—a lower, the Lawston Linn and Muirburn coals (Scremerston position), and an upper, the Kilnholm coals (Lickar position). The Upper Carboniferous Rocks of that region, embracing the Canonbie Coalfield, have been referred by Mr. Kidston to the Lower, Middle, and Upper Coal-measures, in virtue of the evidence obtained from the plants. The bores sunk in recent years near Rowanburn prove that the Rowanburn coals (Lower Coal-measures) overlie the marine limestone group with the Kilnholm (Lickar) coals; and that, further, the Red Sandstones and shales referred by Mr. Kidston to the Upper Coal-measures pass downwards into a series of thin coals which may be the upper part of the Byreburn series. An important economic question arises as to the extension of this coalfield, for it appears that there is good ground for the belief that the sandstones and shales of the Upper Coal-measure age overlie the Middle and Lower Coal-measures. In conclusion, it was shown by means of vertical sections that the Carboniferous succession in Eskdale and Liddesdale resembles more closely that of Northumberland than that of central Scotland.—As an important supplement to the foregoing, Mr. Kidston communicated lists of the fossil plants of the Calciferous Sandstone series of Dunfermline, of the Carboniferous Limestone of Eskdale, of the Lower Coal-measures of Canonbie, of the Middle Coal-measures of Byreburn, and of the Upper Coal-measures of Jockie's Syke, Cumberland, which borders on Dumfriesshire. Tables showing the horizontal distribution of the species were given, and some new and interesting species described, among these a new species of Pinakodendron (*P. Macconochiei*) being the first record of the genus in Britain.—A paper by Prof. **Ewart** on the wild horse will be printed in full in these columns.

DUBLIN.

Royal Dublin Society, May 19.—Prof. W. F. Barrett, F.R.S., in the chair.—Prof. T. **Johnson** gave an illustrated account of a tylose which he had found in a tracheide in the xylem of the rhizome of a bracken fern (*Pteris aquilina*, L.). He suggested that the disturbance in the transpiration current resulting from cutting the bracken might produce tyloses in the underground stem.—Mr. Richard J. **Moss** read a paper on an Irish specimen of dopplerite. This interesting substance does not seem to have been previously recorded as occurring in the United Kingdom, though it would appear from a reference to a peculiar form of peat in a report issued by the Commission on Bogs in Ireland in 1811 that the substance named dopplerite by Haidinger in 1849 had previously been observed in Ireland. The dopplerite recently found in a peat bog in the county of Antrim was in the form of an elastic jelly, velvety-black in colour, and drying to a solid of jet-like appearance, with a bright conchoidal fracture. In chemical composition it differs little from the peat in which it was found. It is shown that mineral matter, chiefly iron oxide and lime, which constitutes 5 per cent. of the dry substance, may be removed by steeping the jelly in hydrochloric acid without altering the consistence or appearance of the substance. The original jelly is acid to litmus, and liberates carbon dioxide from calcium carbonate. Assuming that it consists chiefly of monobasic humic acid with a molecular weight of 350, the gas liberated corresponds to 73 per cent. of humic acid in the dry substance. The peat in which the dopplerite was found liberates carbon dioxide corresponding to 60 per cent. of the dry substance.—Prof. W. F. **Barrett** exhibited and described Hilger's direct-reading wave-length spectroscope.—Prof. E. J. **McWeeney** gave a description of *Streptothrix nigra*, an organism occurring in soil, and producing a bright brown pigmentation of the nutrient medium.

Royal Irish Academy, May 25.—Prof. R. Atkinson, president, in the chair.—Reports were presented by Dr. R. F. **Scharff**, R. L. **Praeger**, Prof. G. A. J. **Cole**, Prof. D. J. **Cunningham**, F.R.S., G. **Coffey** and others on the results obtained during their exploration of the Kesh Caves, Co. Sligo. The reports detailed the results obtained from an exploration of the deposits of clay, rock-fragments, and stalagmite found in the caves situated on the slopes of Keishcorran Mountain in Co. Sligo. Several weeks were spent by the committee in excavating these caves in 1901. The zoological results possess many points of interest. The brown bear was found to have inhabited these caves in great numbers in former times; in Ireland remains of this animal have hitherto been found only very locally. The other animals found in the caves which are now extinct in the country in either a wild or domesticated state were the reindeer, wolf, and Arctic lemming, the last of which is an addition to the Irish fossil fauna. Man was chiefly a late inhabitant of the caves, a single polished axe being the only Neolithic object found. Several implements of crannog type were found, and abundance of charcoal.

June 8.—Prof. R. Atkinson, president, in the chair.—The intrusive gneiss of Tirerrill and Drumahair, by Prof. Grenville A. J. **Cole**. The northern end of the gneissic axis of the Ox Mountains consists of an intrusive granite, which contains blocks of amphibolite, derived from an earlier series. The banded phenomena presented by it are connected with its flow, and the contrasts of mineral constitution in the bands are connected with the abundance of basic inclusions, which have become streaked out in the fluidal mass. Though brought into their present prominence by Caledonian and Hercynian movements, the crystalline rocks of the chain may still be of Archæan age, as originally suggested by Prof. Hull.

PARIS.

Academy of Sciences, June 22.—M. Albert Gaudry in the chair.—Two fluid batteries; electromotive force, condensations, transformations of energy at the electrodes, by M. **Berthelot**.—On the structure and history of the lunar crust. Observations suggested by the seventh number of the photographic atlas of the moon, by MM. **Lœwy** and P. **Puiseux**. This volume contains photographs which show clearly the frequent distribution of the eruptive orifices along the lines of cleavage. From the mode of diffusion of the scoriæ there would appear to have been, at a remote period, an atmosphere, and from the state of these deposits it is clear that there can be no running water on the surface.—On the loss, in time of drought, of a spring fed by infiltration of a sheet of water, by M. J. **Boussinesq**.—On a property of the α-rays of radium, by M. Henri **Becquerel**. If the α-rays, placed in a field of magnetic intensity H, have a real or fictitious mass m, carrying an electric charge e, they ought to describe a circular trajectory of radius R, with a velocity v, and the relation $RH=vm/c$ ought to hold between these quantities. From this RH ought to be a fixed quantity for the α-rays, but this is not the case, since Prof. Rutherford has given $RH=3{\cdot}9\times10^5$, and in the experiments now described values of RH, varying continuously between $2{\cdot}91\times10^5$ and $3{\cdot}41\times10^5$, have been obtained. From this it follows that in a uniform magnetic field the radius of curvature of the trajectory of the α-rays deviated by the field increases with the length of the trajectory, and this may be attributed to the presence of air.—The preparation of carbides and acetylene acetylides by the action of acetylene gas upon the hydrides of the alkalis and the alkaline earths, by M. Henri **Moissan**. At a temperature of 100° C. the hydrides of the alkalis and the alkaline earths react with acetylene, liberating hydrogen and giving compounds of the type $C_2K_2.C_2H_2$ and $C_2Ca.C_2H_2$. These compounds, heated in a vacuum, dissociate readily into acetylene and the corresponding carbide, and hence form a new method for the preparation of the carbides at a low temperature. Neither methane nor ethylene react at 100° C. with these hydrides.—The influence of the solvent on the rotatory power of certain molecules, by MM. A. **Haller** and J. **Minguin**. Details are given of experiments on several camphor derivatives. In solution in benzene and its homologues, which are non-ionising liquids, the rotatory power of cyano-camphor was found to be nearly zero, whilst in other solvents, especially in alkaline liquids, which are strongly ionising, the rotatory power was very high. Other camphor derivatives showed similar results, although the differences were less marked.—The differences between

the diseases known as nagana, surra, and caderas, by MM. A. **Laveran** and F. **Mesnil.** It has been previously shown that the nagana or disease of the tsetse fly and caderas, prevalent in South America, are distinct diseases, and a comparison of the Trypanosoma from the disease known as the surra with the two preceding shows that this is quite different from either. The three diseases are hence quite distinct.—The international congress of savants at the Universal Exhibition of St. Louis, 1904, by M. **Newcomb.** This congress will be held on September 19, 1904, and the five following days. A short account is given of its objects and the arrangements that have been made.—The drawings on the walls of the cave of Altamira (Spain), by MM. Émile **Cartailhac** and the Abbé H. **Breuil.** A comparison is made between these drawings and those recently described in the French caves. The style of work and colouring is similar in both, but in the Spanish cave the colouring is much superior to that in the French caves; it is noticeable that in the former drawings of the mammoth and reindeer are absent.—Remarks by M. Salomon **Reinach** on the preceding memoir. It is noteworthy that only animals which could be used for food are depicted in these caves, there being no representations of carnivora. The Aborigines of Central Australia also draw figures of animals on the rocks and soil, with the object of increasing their multiplication, and here, also, carnivora are naturally absent.—The propagation of waves in elastic media, according as the media are conductors or non-conductors of heat, by M. P. **Duhem.**—The perpetual secretary announced to the Academy the death of M. L. Cremona, correspondant for the section of geometry. —On surfaces which may, in several movements, give rise to a family of Lamé, by M. A. **Demoulin.**—On the simultaneous employment of the laws of distinct survival, by M. Albert **Quiquet.**—On a method of measuring the variation of the current in the armature in short circuit during the time of commutation in a continuous current dynamo, by M. **Iliovici.**—On the physical constitution of the atmosphere, by M. Louis **Maillard.** The usual formula for the density $\rho=273/760\ p/T$ does not appear to hold when p and T are both very small. From the author's calculations, which are partly based on results from captive balloons and partly on laboratory experiments, the density of the air diminishes up to a height of 30 to 50 kilometres, and then increases up to 75 kilometres ($\rho=0\cdot21$). If these results are correct, the theories of astronomical refraction will require some modifications.—On the estimation of vanadium in alloys, by M. Paul **Nicolardot.** The method of Sefström (the solution of the alloy in sulphuric or hydrochloric acid) for the qualitative detection of vanadium in Swedish iron, when slightly modified, can be made quantitative. Comparative analyses of the same sample by three methods are given.—On the esterification of the hydracids, by M. A. **Villiers.**—On the benzoyl derivatives of hydrazobenzene, by M. P. **Freundler.**—On the action of abietic acid on ferments, by M. Jean **Effront.**—On some combinations of chloride of gold and pyridine, by M. Maurice **François.**—The phenyl substitution in the phenylmethanes, their carbinols and chlorides, by M. Jules **Schmidlin.** A thermochemical paper.—The preparation of alkyl nitrates and nitrites, by MM. L. **Bouveault** and A. **Wahl.** Excellent yield of nitric esters can be obtained by the use of anhydrous nitric acid in the case of the primary alcohols; with secondary alcohols the action is quite different, the corresponding ketone being the main product of the reaction; with tertiary alcohols the action is destructive. The action of pure HNO_3 is suggested as a reagent for differentiating between the three classes of alcohols. Excellent yields of nitrous esters were obtained by the action of nitrosyl chloride upon a mixture of the alcohol and pyridine at 0° C.—Chlorine derivatives of methylene chloroacetate and diacetate, by M. Marcel **Descudé.**—On some new members of the pyranic series, by MM. R. **Fosse** and A. **Robyn.**—On stachyose, by M. C. **Tanret.** It is shown that manneotetrose and stachyose are identical, the composition being $C_{24}H_{42}O_{21}$.—Comparisons between the phenomena of nutrition in seedlings with or without their cotyledons, by M. G. **André.**—On some conditions of oxidation of salicylic aldehyde by organs and extracts of organs, by MM. J.-E. **Abelous** and J. **Aloy.** The oxidation of salicylic aldehyde in extracts from the liver of the horse or calf goes on better in a vacuum than in air, the presence of free oxygen diminishing, or even suppressing, the oxidation.—On the glycerol in the blood, by M. Maurice **Nicloux.**—On mixtures of iodine and sulphur, by M. R. **Boulouch.** From a dilatometric study it would appear that sulphur and iodine when fused together give rise to neither definite compounds nor solid solutions.—The action of the magnetic field on the infusoria, by MM. C. **Chéneveau** and G. **Bohn.** Contrary to the results obtained by M. H. du Bois, it is found that an intense magnetic field modifies the ciliary movements, the growth, and the multiplication of the infusoria.—The law of the action of trypsin on gelatin, by MM. Victor **Henri** and Larguier **des Bancels.**—The family of the Clostridiaceæ, by M. Paul **Vuillemin.**—On the structure of the seed of *Nymphaea flava*, by M. J. **Chifflot.**—The disease of the plane tree, by M. J. **Beauverie.**—On the exotic plant species in the immediate neighbourhood of Béziers (Hérault), by M. P. **Carles.**—On the geology of the Oubangui district at Tchad, by M. **Lacoin.**—The poisons of the organism and gestation, by MM. **Charrin** and **Roché.**—The results of phototherapy and the technique of its application in lupus, by M. **Finsen.** Statistics of the results obtained in the treatment of lupus at the Finsen Institute, Copenhagen, with some details of the mode of treatment.

DIARY OF SOCIETIES.

FRIDAY, JULY 3.

INSTITUTION OF MINING ENGINEERS, at 11.30 a.m.—Further Remarks on the Portuguese Manica Gold-field: A. R. Sawyer.—Coal fields of the Faröe Islands: E. A. Greener.—Miners' Anæmia or Ankylostomiasis: Dr. J S. Haldane.—Water-softening Plant: Vincent Corbett.—The Redevelopment of the Slate-trade in Ireland: O. H. Kinahan.—The Smelters of British Columbia: W. Denham Verschoyle.—The Commonsense Doctrine of Furnace-draught: H. W. Halbaum.—The Ventilation of Deep Mines: Arthur C. Murray.

GEOLOGISTS' ASSOCIATION, at 8.—Some Flint Implements from Reading and Maidenhead: Ll. Treacher.

CONTENTS.

THURSDAY, JULY 9, 1903.

RECENT WORKS ON OPTICS.

Manual of Advanced Optics. By C. Riborg Mann, Assistant Professor of Physics in the University of Chicago. Pp. 196. (Chicago: Scott, Forseman and Co., 1902.)

Practical Exercises in Light: being a Laboratory Course for Schools of Science and Colleges. By R. S. Clay, B.A., D.Sc. Pp. vi+187. (London: Macmillan and Co., Ltd., 1902.) Price 2s. 6d.

Elementary Ophthalmic Optics. By Freeland Fergus, M.D., F.R.S.E., Surgeon to the Glasgow Eye Infirmary. Pp. viii + 107. (London: Blackie and Son, 1903.) Price 3s. 6d. net.

Geometrical Optics: an Elementary Treatise upon the Theory, and its Practical Application to the more Exact Measurements of Optical Properties. By Thomas H. Blakesley, M.A. Pp. viii + 120. (London: Whittaker and Co., 1903.) Price 2s. 6d.

Das Stereoskop. Seine anwendung in den technischen Wissenschaften. Über Entstehung und Konstruktion Stereoskopischer Bilder. Von Wilhelm Manchot, Architekt und Professor am Städel'schen Kunstinstitut zu Frankfurt a.M. Pp. vi (3 blank)+ 68. (Leipzig: Veit and Co., 1903.)

MR. MANN'S book contains an account of the three months' experimental course on optics pursued by the senior students at the University of Chicago. The name Chicago, uttered on this side of the Atlantic, suggests many different things to different persons; to physicists it cannot but bring to mind the name of Prof. Michelson, to whom we are indebted for some of the most valuable and ingenious optical investigations that the last century brought forth. An experimental course, developed according to the ideas of Prof. Michelson, could scarcely be other than original and stimulating; the course before us, in addition, is systematically developed, the descriptions are clear and concise, and the illustrations, though few, are well calculated to serve the purpose for which they were intended. Each chapter commences with a brief theoretical investigation, wherein the aim is to concentrate attention on the physical, as distinguished from the purely mathematical, aspect of the subject; following this is a description of the experiments, and the manipulation of the necessary apparatus. Room is left for the student to develop a certain amount of originality in his methods, and thus avoid reduction to the state of a mere mechanical copyist. Numerous references are given to original memoirs, which should prove very useful to advanced students. Besides the experiments usually found in books on optics, descriptions are given of the method of determining the resolving power of telescopes, spectroscopes, and gratings. It is interesting to find Prof. Michelson's classic researches on the resolution of spectral lines by means of the interferometer included in a course for students. In fine, no one on glancing through this book would hesitate to endorse the concluding words of Prof. Michelson's introductory note:—

"Those who desire to enter into optical investigations cannot get a better foundation for future work than by studying the optical theories here presented, and performing the experiments described."

Teachers have long felt the want of an inexpensive book on practical light, suitable for students who are commencing the study of the subject; and to these Dr. Clay's little book may be confidently recommended. As stated in the preface, it forms the elementary portion of a "Treatise on Practical Light," now in preparation by the author. It is by no means an easy task to arrange a series of elementary experiments on light, which shall be sufficiently varied to prevent the interest of the student from flagging, while of sufficient scope and completeness to give the student a firm grasp of the elementary principles of the subject. The author is to be congratulated on his success in both the above respects. The ordinary laws of reflection, refraction, and dispersion are illustrated by the aid of simple experiments, which can be performed without the aid of expensive appliances; indeed, the spectrometer is the only piece of elaborate apparatus required for the course described. In addition, numerous practical exercises are appended at the ends of the chapters. Attention is directed to the observation of caustics, and the principle of formation of the rainbow. The optical bench described by the author is to be commended for its simplicity and efficacy. Perhaps the most novel part of the course consists in a number of experiments on the optical properties of the eye, and others on diffraction and interference. We do not remember to have previously seen a description of the method of producing Lloyd's single mirror fringes by the aid of a prism and spectrometer. Points to which objections can be raised are neither numerous nor important. On p. 86, it is stated that a telescope focused for infinity and directed towards the sun gives rise to a parallel bundle of emergent rays. This is scarcely correct; the rays from any particular point of the sun will emerge parallel to each other, but the total emergent light consists of a diverging bundle of pencils, each consisting of parallel rays. On p. 127, it is stated that the *fovea centralis* contains rods only and no cones, while the reverse is actually the case. The account given on p. 132 of the mechanism of accommodation could bear revision; modern research indicates that the increased curvature of the anterior surface of the crystalline lens is produced by an increase of tension in the anterior capsule layer, and not by its relaxation, as was supposed by Helmholtz.

The opththalmic surgeon has to deal with the eye, not alone as a delicate organ of the human body, subject, like other organs, to disease; but also, in many cases, as a defective optical instrument. Hence a knowledge of optics is as necessary to him as an acquaintance with the science of electricity is necessary to the electrical engineer. Dr. Fergus's book has been written for medical students, as an elementary introduction to the science of geometrical

optics. There are few points in this book calling for remark, except, perhaps, the very arbitrary limitations of the subject-matter. Thus, chromatic aberration and dispersion, the "power" of a lens and its measurement in dioptres, the use of lenses as spectacles or magnifying glasses, and the optical system of the eye itself, alike remain unmentioned. The mathematical theory of thick lenses is discussed, although the subject of lens combinations is neglected. No experimental methods with regard to lenses are described, and no problems for solution by the student are appended.

In taking up the study of light, students generally commence with the laws of geometrical optics. Further on in their studies they find that the instruments used for even the simplest investigations comprise various combinations of lenses and mirrors, which can be understood and appreciated only when a competent knowledge of geometrical optics has been acquired. In spite, however, of the manifest importance of this branch of knowledge, it has in recent years received scant attention from investigators, and has shown few marks of progress. This is undoubtedly due in part to the fact that the subject of geometrical optics affords a happy hunting-ground for the mathematician, who may, or may not, have anything more than a passing acquaintance with the practical side of the subject; while the attention of experimental investigators has mostly been absorbed in other directions. Let us consider, for instance, the subject of lens combinations. Gauss showed that a thick lens, or combination of lenses, possesses four important points on the axis—the two principal points and the two principal foci. If the distances of the object and image are respectively measured from the first and second principal points, then the formula for the combination takes a form similar to that applicable to a single thin lens. In a sense, then, the work of Gauss affords a complete method of solving any problem connected with lenses; it labours under the disadvantage, however, that in most problems the necessary analysis is of a somewhat clumsy character. It has thus been left for Mr. Blakesley to introduce a remarkable simplification, by measuring the distances of the object and image, not from the first and second principal *points*, but from the first and second principal *foci*. The resulting equations in u and v, as well as those relating to the magnification, now take forms amenable to simple analytical treatment. The focal length of a lens, or lens combination, is taken as a constant of one dimension in space, not necessarily measured from any particular point; in this respect it resembles the coefficient of self-induction of a coil.

The advantage of this method is well illustrated by the investigation on the combination of a lens and a mirror, on pp. 67–71. It also readily adapts itself to the needs of experimental investigations. A distinguishing feature of the book is the attention devoted to practical determinations of the constants of lens systems; those involving the use of a microscope are particularly worthy of remark, though all are interesting. It is to be regretted, however, that Mr. Blakesley has preferred to speak of Gauss's principal points as "the points 1 of the diagram"; a section on the graphical construction of images, using Gauss's principal planes, would also make many problems clearer. In view of their practical importance, with respect to the optical system of the eye, Listing's nodal points also claim some mention. Chapter xi., on forms of lenses for minimum deviation of rays, is of great interest and practical importance. It is to be feared, however, that the geometrical relations of circles, which are cursorily alluded to in the text as "quite clear," may greatly puzzle many students whose leaning is toward practical physics rather than toward pure mathematics. Further, the theory of the achromatisation of an eye-piece (p. 110) could bear amplification. Many students arrive at the conclusion that Huyghens's eye-piece has advantages, with respect to ordinary chromatic aberration, over a single thin lens used as a magnifying glass—a conclusion which is demonstrably erroneous. Mr. Blakesley gives data from which a student, if sufficiently enthusiastic and persevering, might arrive at the truth of this matter; but a page or so devoted to the question would have enhanced the value of the book. It is further to be regretted that a series of problems, to be solved by the student, has not been appended; a loose leaflet containing five such problems, issued as advertising the scope of Mr. Blakesley's book, shows how attractive work of this kind may be made. Finally, however, it must be said that a more interesting and stimulating book than that under consideration is seldom likely to come in the way of the student. Mr. Blakesley has, moreover, effected a notable advance in geometrical optical theory.

The stereoscope is probably mentioned, more or less briefly, in most lecture courses on optics; but it is seldom realised that this instrument is something more than a plaything or a scientific curiosity. Yet it is undeniable that, in many branches of science, the stereoscope could be used as a most valuable aid to instruction. In commencing the study of analytical geometry of three dimensions, for example, the chief difficulty of a student is to realise the actual significance of the more or less conventional diagrams which he must use; there can be little doubt that, if provided with proper diagrams to be viewed stereoscopically, he would avoid much profitless labour, and gain, in the end, much clearer notions of the significance of the processes employed. In practical solid geometry, architecture, crystallography, &c., there are other wide fields for the use of the stereoscope. Prof. Manchot mentions a further novel use to which the stereoscope can be put. If two bank notes are viewed stereoscopically, slight differences, which could scarcely be detected by the eye, will give the printing an appearance of relief or depression, so that a false note can easily be detected.

That the stereoscope is not more largely used is doubtless due to the fact that, in the forms ordinarily met with, the pictures or diagrams are limited to too small a size for the full benefit of the instrument to be felt. Prof. Manchot has invented a stereoscope which can be adapted to viewing diagrams of any size whatever, and this instrument is fully described

as well as the method of constructing stereoscopic diagrams to be used with it. To those anxious to lighten, so far as possible, the labour of the student, while increasing the efficiency of the teacher's efforts, Prof. Manchot's little book should afford suggestive reading. EDWIN EDSER.

PREVENTION OF ACCIDENTS IN FACTORIES.

Infortuni sul lavoro. Mezzi Tecnici per Prevenirli. By Ing. E. Magrini. Pp. xxxi+251. (Milano: Ulrico Hoepli, 1903.) Price L.3.

THE introduction opens with this apt quotation, "Le fabricant doit autre chose à ses ouvriers que le salaire." And the book purposes to teach the manufacturer how to pay the debt by providing all the protection possible against dangers attending the use of machinery.

The prevention of accidents is a subject to which much attention has been given in Italy, first by the "Associazione per prevenire gli infortuni sul lavoro," and finally by the Government, which completed its legislation in 1899 by the issue of a set of precautionary rules incumbent on all users of machinery. These rules form the framework of the book, each chapter having, as text, an extract from them, and describing in detail the appliances needed to give effect to the regulation in the various classes of machinery.

The first two chapters deal with prime movers, the means of fencing them and of stopping them, not merely by cutting off the motive power, but by applying brakes to the moving parts. Transmissions—shafts, belts, gears, &c.—form the subject of chapter iii., and share with circular saws (chapter v.) the distinction of causing more accidents than any other class of apparatus. A comparison of these two chapters is instructive. Of all protective devices, those for circular saws have called for most ingenuity and met with least success. The numerous coverings described are costly and complicated without being really effective, and they are devices which a workman would discard whenever possible. On the other hand the protections described in chapter iii. are simple, effective, and devoid of any hindrance in working, and call for more attention than they usually receive. Carding and spinning machines, emery wheels, ladders and protective clothing, spectacles, &c., are dealt with briefly, while elevators of all kinds and their safety appliances are discussed fully. In chapter vii. forty pages are devoted to the dangers of manœuvring with belts in motion. Much in this is of great value, many of the devices being as simple as they are effective.

Electrical machines, fires and boilers receive very inadequate treatment in the remaining twenty-five pages. The chapter on electrical machinery does not approach the standard of the rest of the book; it is far from complete, even on more important points, and contains many statements and recommendations that would find but little acceptance from engineers.

Speaking of the book as a whole, it tends rather towards a catalogue; more critical descriptions of the different devices would have been welcome, and this more especially in regard to two important points, which are almost entirely overlooked. These are, firstly, that a device which does not afford complete protection often increases the danger; it lulls to a sense of false security. Secondly, that a protection which can be discarded by the workman is of far less value than one which he is forced to adopt. Most safety devices are of some hindrance in working, and experience shows that workmen take no interest in efforts made for their protection; they are merely annoyed at the inconvenience in their work.

These few criticisms are easily outweighed by the praise which the book well deserves. Nearly all the devices are illustrated as well as described, and in matters of detail the book gives numberless useful hints, and what may be termed dodges rather than appliances; a master, by following these, could avoid many dangers at little cost and trouble.

G. H. BAILLIE.

A NEW SWISS HANDBOOK.

Guide to Switzerland. Pp. cvi + 235; with 31 maps and 6 plans. (London: Macmillan and Co., Ltd., 1903.) Price 5s. net.

MODERN tourists, and in particular those who wander in companies, are prone to haunt certain familiar centres, Lucerne, Grindelwald, Zermatt, Chamonix, Pontresina, and to confine their excursions within narrow bounds. Messrs. Macmillan have designed a handbook to meet the needs of this class. In many respects the conception of the volume is good, but the execution is faulty and unequal. To deal first with its merits. The eulogy of the political institutions of the Swiss Republic, and the notes on the nature of glaciers, introduced among the preliminary chapters, ought to interest and inform the better class of sight-seers, while practical suggestions on health and outfit are useful to all. The separate hotel list will be found convenient for reference; houses frequented by our countrymen are distinguished by larger type, and prices are in many cases quoted. As a whole, the list seems to be compiled with care, but there are singular omissions; amongst them we have noted Binn, St. Beatenberg, Montana, Piora, Promontogno, Lanzo d'Intelvi, all well-known stopping places. At Binn, the text tells us, "refreshments can be procured, and if necessary beds obtained at the Curé's." The village has for years had a large hotel with an English chaplain attached. The inns on the tour of Mont Blanc, at Contamines, Nant Borrant, Chapieux, are mentioned in the route, but not in the list.

When we come to study in detail the guide-book proper, we find that the routes have been conveniently arranged round the centres to which they naturally attach themselves. The editors recommend their text as "concise and accurate." As to accuracy, we cannot endorse their estimate of their work. The section relating to Davos is well done, but that devoted to the Upper Engadine is meagre and untrustworthy. The new railway connecting Thusis and St. Moritz by the Schyn and Albula, opened to Celerina this year, ought to have been described. Promontogno, with its good hotel, the natural halting-place for travellers

coming from the Lake of Como, and the exquisite drive to Soglio, are passed over. The "Palace Hotel" at Maloja has its prospectus printed almost in full, but many of the excursions from it are catalogued under Sils. The carriage roads up the Fex Thal and Roseg Thal, the restaurants at Curtins, on the Surlei Furka, Piz Languard, and elsewhere, are left out, though in other districts restaurants are noted. The Bernina Hospice and Bernina Houses have been confused. The inn at the foot of the Morteratsch Glacier and that on the Diavolezza Pass, the latter the best starting point for many peaks and passes, are ignored. The way to Boval is said to be "rough and over snow"; there is an excellent path; so there is, since 1902, up Piz Julier, said to be "difficult." The Alp Misaun is suggested as a starting point for Piz Morteratsch. No travellers prefer its hay to the good accommodation offered by the Roseg Inn or the much higher Tschierva hut.

It is an easy task to pick holes in a guide-book covering such an extensive field as Switzerland. We have preferred to collect our bundle of blunders almost entirely from a single district. We could easily have made it bigger without going farther, and by extending our survey we might fill columns. But enough has been done to warn travellers who may be tempted by the numerous and, as a rule, excellent maps to purchase this volume that they must not rely on its information as regards either ordinary excursions or glacier expeditions. Nor in many cases can we at all agree with the editors' estimates of scenery. We should hesitate to call the Bel Alp "a beautiful and secluded village," or to characterise "the scenery round the Borromean Islands" as "strikingly grand." The index stands in need of careful revision.

OUR BOOK SHELF.

The Fauna of British India, including Ceylon and Burma. Published under the Auspices of the Secretary of State for India in Council. Edited by W. T. Blanford. Hymenoptera. Vol. ii. Ants and Cuckoo-Wasps. By Lieut.-Colonel C. T. Bingham. Pp. xix+506. (London: 1903.)

THE first volume of this work appeared in 1897, and included the wasps and bees, and now the second volume has been issued, containing the still more interesting family of the Formicidæ, and also the small, but very beautiful, family of the Chrysididæ, or ruby-tail wasps; or, as Colonel Bingham calls them, the cuckoo-wasps. This completes the important section of Aculeata, or stinging Hymenoptera, and the monographing of the remaining groups, which are still very imperfectly known, is very properly deferred for the present. We are, however, pleased to see that Colonel Bingham has undertaken to prepare a work on the butterflies of British India for the same series.

Colonel Bingham divides the Formicidæ into five subfamilies, Dorylinæ, Ponerinæ, Myrmecinæ, Dolichoderinæ, and Camponotinæ (498 species); and Chrysididæ with four subfamilies, Cleptinæ, Ellampinæ, Chrysidinæ, and Parnopinæ (79 species). When we remember that instead of 498 species of Formicidæ there are only about forty species in Britain, and only about a hundred in all Europe, the difference between a temperate and a tropical fauna becomes sufficiently obvious.

A very clear account of the external characters of ants is given in the introduction, elucidated by numerous figures of structure. The bulk of the work is almost exclusively descriptive, but includes useful keys to genera and species, synonymy, and occasional notes on habits. Exigencies of space necessitate the latter being of the utmost brevity, which, though obviously unavoidable, is none the less to be regretted, for the habits of many Indian ants are extremely interesting.

The 577 species described by Colonel Bingham in the volume before us are illustrated by 161 text illustrations, frequently including structural details as well. Occasionally more than one species of a genus is figured. A coloured plate is added, with sixteen coloured figures of Chrysididæ. Among the most interesting of the uncoloured figures are those representing the curious spiny ants of the genus Polyrhachis.

Comparatively few new species are described, for much has been written on Indian Formicidæ in recent years. But, except as regards the obsolete catalogue of F. Smith, almost all that has been published is scattered through a variety of scientific periodicals not always easy of access, and we congratulate Colonel Bingham on the completion of a comprehensive work which must greatly facilitate the study of his subject to all future workers.

Dendrologische Winterstudien. Von Camilla Karl Schneider. Pp. vi+290. (Jena: Gustav Fischer, 1903.) Price 7.50 marks.

THE study of our tropophytic trees and shrubs in their winter condition has been somewhat neglected from the systematist's point of view. While such works as those of Sargent and Willkomm have hitherto supplied the wants of the forester, still the number of species they deal with is limited, and a more extended list is required. To meet this want the author of the above work has set himself no small task, and, in our opinion, has achieved a degree of success which only great patience and perseverance could attain. The book deals with 235 genera, including 434 species of indigenous and introduced deciduous trees and shrubs in Europe. A notable feature of the work is the large number of illustrations, 224 in all, which are reproduced from photographs and hand drawings of actual specimens.

The subject-matter is divided into three sections—a general, a special, and a systematic. The first section deals with general organography, and gives a wide and comprehensive survey of the subject. The reader is thereby well prepared for what is to follow in the next section, which is the bulkiest and most important one in the book. It is devoted to the special consideration of the various species in their winter condition. The descriptions are short and concise, many abbreviations being used, which are, however, fully explained at the beginning of the section. The accompanying figures, which illustrate the salient features of the species described, are very instructive and well drawn. The author attaches more importance to good figures than to descriptions, and has consequently produced a large number of drawings which alone would, in most cases, amply suffice for purposes of identification and comparison. The classification of the leafless twigs is somewhat intricate, but this is unavoidable when a large number of species has to be tabulated. Following this comes a section giving a systematic arrangement of the various species dealt with. The system adopted is that of A. Engler.

In the bibliography at the end, the more important dendrological works are cited, and a short statement of their contents given.

The work is primarily a contribution to systematic dendrology, and cannot fail to be of interest and value to the systematist. At the same time, the subject is of considerable importance to the practical man, be he nurseryman, forester, gardener, or landscape gardener. In those professions winter operations often occur, in which it is very important to be able to identify accurately the different species.

The special descriptions of the species dealt with in the book, so far as they have been tested, have proved to be quite accurate. There are a few misprints and slips, which are, however, corrected in the errata at the end of the book. There are one or two emendations still required, such as "*Spartium junceum*" instead of "*Sportium unceum*," p. 22, line 3. Also in the reference to the wood body of Fig. 31, given on p. 56, line 33, we would substitute "undermost layer" for "uppermost layer." However, such slips will, no doubt, disappear in a second edition, which we hope to see this work reach, and in which the author will be able to enhance the value of his work by the addition of still more species.

La Tecnica delle Correnti Alternate. Vol. i. Parte qualitativa e descrittiva. By G. Sartori. Pp. xv+336; 260 illustrations. (Milano: Ulrico Hoepli, 1903.) Price L.8.

THE course of evening lectures read before a class of artisans is here given in book form. Except for an occasional algebraic expression, mathematics are rigidly excluded, and yet the author tackles the most complex phenomena of alternate currents, and discusses the behaviour of synchronous, asynchronous and rotary-field motors, with their various starting devices; of rotary converters and their tendency to hunt; of alternators running in parallel, and of wave propagation in long lines. And he does this with so much success that the usual treatment on the basis of a sine wave-form compares unfavourably. A mathematical treatment of the subject is practicable only on the assumption of sine-waves, and the evil of this is that students are apt to forget that in practice the wave-form is rarely sinusoidal, and generally so far removed from it that the theoretical deductions are then valueless. To deal with alternate currents is far harder without than with the use of sine waves, and the author is to be congratulated on his success. The book, in fact, is not an elementary manual, but an up-to-date treatise, its language suited to the artisan and its substance to any student.

Monographie des Cynipides d'Europe et d'Algérie. Par l'Abbé J. J. Kieffer, Membre de la Société Entomologique de France. Tome Second. Premier Fascicule. Pp. 288; avec les planches 1 à 9. (Paris: Hermann, 1903.) Price 16 francs.

THIS is another instalment of the important series of monographs forming part of the great work on Hymenoptera inaugurated by the brothers André. It includes the portion of the parasitic Cynipidæ comprised in the tribes Allotriinæ, Eucœlinæ, and the commencement of the Figitinæ. The Allotriinæ must be regarded as very useful insects, for they feed chiefly, if not exclusively, on Aphidæ and Coccidæ; whether they ever attack other insects seems for the present to be somewhat uncertain. The Eucœlinæ, on the other hand, are parasites on the larvæ and pupæ of Diptera, and sometimes on small Coleopterous larvæ, and the single recorded instance of their attacking Aphidæ is considered by Kieffer to require confirmation, while the known larvæ of the Figitinæ are parasitic on the larvæ of Diptera, Coleoptera, and Neuroptera.

The subject is treated in a similar manner to that of the first volume, which we have recently noticed, and several species are described as new. The former standard of excellence is well kept up, both as regards the text and plates.

Spirals in Nature and Art. By Theodore Cook. Pp. xxi+200. (London: John Murray, 1903.) Price 7s. 6d. net.

THAT spiral curves, or, more strictly, helices, and screw motions should play an important part both in the natural world and in structures constructed by human hands is a fact for which a mathematician can easily suggest an explanation on general grounds. Without professing to bring any extensive scientific or technical knowledge to bear on the subject, Mr. Cook has made a most interesting study of the resemblances between the spiral forms occurring in nature and in art, and has produced a book the study of which will be a delightful recreation to any class of reader. Apart from the mere spiral form, Mr. Cook finds remarkable resemblances between the structure and sculpturing of certain staircases in France and those of the shells of certain mollusca. It is certain that Leonardo da Vinci studied shells, and that he was in France about the time when these staircases were built, and an obvious connection suggests itself. While the author's study of the works of Leonardo da Vinci—illustrated by copies of his drawings—is interesting, the connection of Leonardo's studies of the flight of birds with spiral curves strikes a reader as somewhat doubtful. Even Pettigrew's figure-of-eight-shaped curve, and the oval curve familiar to readers of Marey's "Vol des Oiseaux," which represent, according to modern views, the relative paths of points on the wings of a wasp and a bird, can hardly be said to produce a *spiral* curve when compounded with the forward motion of the animal.

Lois générales de l'Action des Diastases. Par Victor Henri. Pp. xi+129. (Paris: A. Hermann, 1903.)

AFTER a general introduction on catalysis and a classification of catalysers, the author gives a historical account of the work already done on the action of diastases. Then follows a description of his own researches on the action of invertase on cane-sugar, together with the theoretical deduction of a formula which represents with considerable accuracy the actual course of the reaction under varying conditions of concentration. The book concludes with two short chapters on the action of emulsin on salicin, and of amylase on starch. The author shows an intimate acquaintance with the mode of application of the laws governing the velocity of chemical action, and has been successful in selecting appropriate experiments to solve the problem with which he was confronted.

Sylviculture. By Albert Fron. Pp. xii+563. (Paris: J. B. Baillière et Fils, 1903.) Price 5 francs.

THIS is one of the volumes of the useful "Encyclopédie Agricole" which is appearing in France under the auspices of a "Réunion d'Ingénieurs agronomes." It deals succinctly with the methods of cultivation of woods for commercial purposes, gives an account of the chief timber trees, and also deals with the products of forests and the manner of their conversion, in accordance with French practice.

The book has no special feature. It is well adapted to the requirements of students of the "École Nationale d'Agriculture," for whom it is intended, and forms a useful addition to its series without replacing the larger text-books on the forestry of France—such as those of Boppe.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radium and Solar Energy.

THE extraordinary discovery that radium has the property of continuously radiating heat without itself cooling down to the temperature of surrounding objects may possibly afford a clue to the source of energy in the sun and stars.

Taking the Curies' observation that one gram of radium can supply 100 calories per hour, I thought it would be of interest to compute how much radium would suffice to supply the sun's output of energy.

Taking from Langley's observations that this is equal to 828,000,000 calories per square cm. per hour, I find that 3·6 grams of radium per cubic metre of the sun's volume would supply the entire output.

It may be possible that at solar temperatures radium is capable of much more energetic radiation, and, if so, the 3·6 grams might be reduced to a much smaller figure.

Daramona, July 1. W. E. WILSON.

"Red Rain" and the Dust Storm of February 22.

IN a letter under the above heading which you did me the honour to print in your issue of May 21, vol. lxviii. p. 53, I gave the results of the chemical examination of a sample of dust collected from the roof of Bayham Abbey, Lamberhurst, after the dust storm of February 22, and sent to me by the kindness of Lord Camden, and I stated that it would be interesting to compare its characters with those of the dust, presumably of African origin, which was observed to fall in the district of Taormina by Sir Arthur Rücker, and was the subject of an interesting communication to NATURE by Prof. Judd in 1901 (vol. lxiii. p. 514).

Thanks to the kindness of Prof. Judd, who sent me about a gramme of the Taormina dust collected by Sir Arthur Rücker and placed among the geological specimens at South Kensington, I have been enabled to make the comparison.

In external characters the Taormina dust closely resembles that from Bayham Abbey. Its microscopical features are also generally similar.

Mr. C. Simmonds, of the Government Laboratory, to whom I am indebted for the analyses already published, found that after drying at 100° C., the sample had the following composition:—

	Per cent.
Silica	36·32
Alumina	16·35
Ferric oxide, with traces of manganese oxide	6·08
Cobalt oxide	0·32
Lime	6·24
Magnesia	2·21
Sodium oxide	2·59
Potassium oxide	2 72
Water and organic matter	23·49
Chlorides and sulphates	traces
Carbonic acid	3 68
	100·00

The cobalt oxide may include a little nickel, but the quantity was too small to identify with certainty.

After being heated to redness, 28·08 per cent. of the sample was dissolved on boiling with dilute hydrochloric acid, the soluble constituents being:—

	Per cent.
Silica	0·88
Alumina	10·16
Ferric oxide	5·52
Lime	6·24
Magnesia	2·21
Alkalis	2·57
Carbonic acid (by difference)	0·50
	28·08

The organic carbon in the sample amounted to 9·89 per cent., and the organic nitrogen to 0·16 per cent. This small proportion of nitrogen shows that the organic matter is mainly, or entirely, of vegetable origin. Calculated from the mean proportion of carbon in cellulose and humic acid, the amount of organic carbon present in the sample would correspond to about 19 per cent. of organic matter, or, from cellulose alone, to 16½ per cent.

A comparison of the dust from Taormina with the "red rain" dust from Bayham Abbey may be made by calculating the inorganic constituents as percentages on their sum, after deducting water and organic matter:—

	Taormina Dust. Per cent.	Bayham Abbey Dust. Per cent.
Silica	47·47	50·53
Alumina	21·37	20·18
Ferric oxide	7·94	7·23
Cobalt oxide	0·42	—
Lime	8·16	9·50
Magnesia	2·89	2·04
Sodium oxide	3 38	1·27
Potassium oxide	3·56	2·53
Carbonic acid	4·81	6·72
	100·00	100·00

Reduced thus to a common basis for comparison, the inorganic portions of the two samples show a general similarity of composition, the chief differences being that the Bayham Abbey specimen contains a little more silica and chalk, and a little less alumina and alkalis, than the sample from Taormina.

The constituents soluble in dilute hydrochloric acid may similarly be compared, after deducting carbonic acid and raising the figures to percentages:—

	Taormina Dust. Per cent.	Bayham Abbey Dust. Per cent.
Silica	3·19	2·28
Alumina	36·84	39 93
Ferric oxide	20·02	19·35
Lime	22·62	29·20
Magnesia	8·01	4·03
Alkalis	9·32	5·21
	100·00	100·00

It is of interest to compare the foregoing results with an old analysis by Gibbs of dust which fell on a ship in the Atlantic (*Pogg. Ann.*, lxxi., 367). After deducting 18·53 per cent. of water and organic matter, the composition was found to be as follows:—

	Per cent.
Silica	45·58
Alumina	20·55
Ferric oxide	9·39
Manganic oxide	4·22
Calcium carbonate	11·77
Magnesia	2·21
Potash	3·64
Soda	2·33
Cupric oxide	0·31
	100·00

Except for the presence in this sample of a notable quantity of manganese and copper, the analysis bears a close resemblance to that of the Taormina dust; the fact of the similarity is particularly interesting, considering that something like half a century has probably elapsed since Gibbs's sample was collected.

Mr. J. J. H. Teall, the director of the Geological Survey, kindly sent me a sample of "blood rain" dust which fell at Palermo at about the same time as the dust from Taormina collected by Sir Arthur Rücker. This closely resembles the Taormina dust in general characters. Mr. Teall has suggested that the question of the origin of the dust might be elucidated if the samples were found to contain free aluminium hydroxide. The bearing of this upon the question of origin is as follows:—Evidence has been recently adduced to show that laterite, a decomposition-product of the felspars, is an aluminium hydroxide, though always mixed with more or less silica. This type of decomposition, it is believed, occurs only in tropical regions, and hence the presence of uncombined alumina in the dust

if it could be established, would be evidence of tropical origin.

Following out Mr. Teall's suggestion, the Taormina sample, and also the one from Bayham Abbey, have been examined to see if any evidence could be obtained showing the presence in them of aluminium hydroxide. A study of the actions of solutions of caustic and carbonated alkalis upon the dusts showed that both silica and alumina could be dissolved from them by the former solvent; but similar results were also obtained from orthoclase and oligoclase, whilst the treatment with sodium carbonate showed that no large quantity of amorphous silica was present in either of the specimens. The results are not conclusive, but, so far as they go, they point to there being no uncombined alumina in the samples. T. E. THORPE.

Dust Storms in New Zealand.

AN event of more than ordinary interest occurred here last November, and seeing that it has a certain importance not altogether restricted to us and our neighbourhood, I have ventured to address you on the subject.

From Invercargill, at the extreme south of the South Island, it was reported on November 14 that in various parts of the town and district tank water had a clayey appearance, and exposed objects were covered with a fine dust or mud. A similar report came from many places in the south-east portion of the island, and inland as far as Wakatipu, where heavy gales and thunderstorms are stated to have occurred on that date. At Dunedin no sign of the dust was visible during the day, but in the evening, from 8 to 10 p.m., the moon was at times obscured by clouds of a reddish colour, but the weather kept dry and no dust fell. At Waipawa, near the east coast North Island, a very heavy dust storm commenced at 9 a.m. on November 15. It lasted for several hours, extended, and became very thick. It was not due to local causes.

Samples of the dust examined by a local authority in Dunedin were stated to be of volcanic origin, and possibly connected with eruptions in Samoa or in South Victoria.

Dr. Benham, of the Otago University, kindly gave me a sample of the dust that fell at Otakaia, a few miles south of Dunedin. I submitted it to microscopical and chemical examination with the following result:—

The specimen was in a small bottle with water; it had fallen into a bucket which was quite clean, and in such a position that contamination was impossible. The sediment was of a reddish-brown colour, very fine in grain. A mounted specimen examined with an ⅙-inch objective showed various vegetable cells, apparently portions of the feathery pappus of fruits of composites and similar light matter. Small rounded grains of inorganic matter were frequent, in some cases large enough (0·03mm. diameter) to depolarise light. They were chiefly quartz, but some were apparently augite, and others particles of weathered minerals coloured red with iron oxides. To these last the colour of the dust in mass was due. There were also in every preparation observed several diatoms. In one preparation there was a piece of vegetable tissue composed of fine cells. In all there was much carbonised matter. A partial quantitative analysis gave the following result after complete drying in an air bath:—SiO_2 53·68, Al_2O_3 18·44, Fe_2O_3 6·54, CaO 0·95, MgO 1·52, K_2O 2·58, Na_2O 1·67. Loss on ignition, 14·60. Total, 99·98. I have been unable to find any analysis of dust borne any great distance by wind with which to compare this. A partial analysis of dust collected in England, given in a March number of your paper, does not differ much from this except that the loss on ignition is 36·4, and the other constituents correspondingly lower.

There is no doubt that this dust was derived from a desiccated surface; the carbonised matter suggests that it had been swept by fire, and as the weather all over New Zealand had been very wet for weeks previously, there is no possibility of a local origin of the dust.

Since Australia had just previously, after a period of most prolonged drought, suffered from the effects of severe gales, causing dust storms that produced almost total darkness in Melbourne and Sydney, it is natural to look to that continent for the origin of the dust storm. Through the kindness of Prof. J. W. Gregory, F.R.S., I was sent a specimen of dust that fell in Gippsland during a dust storm on October 11, and this, though coarser, was so essentially similar to our dust that a comparison of the two specimens at once established the extreme probability of identity of origin.

The distance in a straight line from Melbourne to Invercargill is 1200 miles, and to Dunedin 1300 miles, and from Sydney to Waipawa 1300 miles. The origin of the dust was probably some distance to the west of the Blue Mountains. There seems, therefore, no doubt that this dust was carried 1500 miles, 1200 of which was over a water surface.

Your readers are doubtless aware that the climate of New Zealand, and of Australia on its eastern seaboard, is chiefly dependent on the passage of deep cyclonic disturbances travelling in a general N.W.–S.E. direction. In front of the centre of these the wind blows strong from the N.W., and behind the centre from the S.W. The barometrical and weather records appended show that at the date mentioned such a cyclonic disturbance of rather more than the average intensity was experienced at the time of the dust fall.

In connection with this I may mention that after the famous "Black Thursday" in Melbourne, Dunedin and the southern portion of the south island of New Zealand generally experienced a dense smoke, and comparatively large fragments of carbonised vegetable matter fell.

In conclusion, I should like to point out the significance of such an observation as this in connection with the distribution of plants in the Southern Hemisphere. Since diatoms and vegetable particles of recognisable size were present in the very small portion of the dust examined, it seems quite possible that in the large total of dust that fell some of the smaller and lighter seeds of Australian plants may have been present.

P. MARSHALL.

Otago University, Dunedin, New Zealand, May 3.

Science and Naval Promotion.

THE friends of the advancement of science in the Navy can hardly fail to be very pleased with the recognition it has received in the recent promotions to the rank of commander. Of the twenty-seven lieutenants promoted on June 30 last, twenty-one were "specialised officers." In a batch of promotions such as this there is much to encourage our best officers to direct their attention to the more scientific work of their profession, yet one cannot but remark upon a feature in the analysis of these promotions, namely, the marked difference in the average times these new commanders remained lieutenants. Thus, three lieutenants (T) averaged 10 years; nine lieutenants (G) averaged 10·5 years; nine lieutenants (N) averaged 12·2 years. This is anything but encouraging to the specialist in navigation, but in view of the immense importance of securing the best men to navigate our fleets and handle them in action, it is much to be hoped that in future lieutenants (N) will not be so heavily weighted on their way to the higher ranks of the service. It is, however, only just to add that the theory and practice of navigation under recent legislation have been placed in a position in the front of scientific education they never occupied before. N. G. T.

Purple Flowers.

IT is generally thought that purple flowers are due to selection by bees, and the small number of blue and purple flowers in New Zealand is accounted for by the supposed

absence of bees. This, however, is hardly correct, for there are several species of native bees in New Zealand which constantly visit composite flowers. But *Pleurophyllum speciosum* has very conspicuous purple flowers, although it is found only in Campbell and Auckland Islands, where there are no bees or flower-visiting moths. Nor does it stand alone, for *Celmisia vernicosa*, and its ally *C. chapmani*, are the only species of the genus with purple discs, and yet they also are only found in Campbell and Auckland Islands. In *C. vernicosa*, also, the leaves have become rigid, although no animal feeds upon it.

I think that these facts are of sufficient interest to bring to the notice of botanists, at a time when, perhaps, we too readily accept selection as the explanation of every character. For in these Antarctic islands the conditions of life are so simple that we can eliminate many causes which complicate the same problems in areas with more varied life.

F. W. HUTTON.

Christchurch, New Zealand, May 23.

The Origin of Variation.

THE following argument may be of interest to your readers, if, as I suspect, it has never been thus formulated before.

In order to account for the origin of species, we must assume that the tendency of an individual to vary is handed down to future generations by appropriate modifications in the transmitted germ-plasm. But, unless we believe in the inheritance of acquired characters (for which we have no certain evidence), the tendency of the first individual to vary can only have become manifest if it had originated in a modification of its own parents' germ-plasm; otherwise that tendency could not have been inherited. Leaving out of account the play of changing external conditions, we are thus forced to regard the variability of individuals as the result of variations in the parental germ-plasm. The problem is, how are such variations produced?

CHARLES S. MYERS.

Gonville and Caius College, Cambridge, June 29.

THE BRITISH ASSOCIATION.

THE Southport meeting of the British Association will begin on Wednesday, September 9. The local arrangements, which have been in the hands of a large and representative committee for many months past, are now well advanced, and give every indication that the meeting will not fall short of that held in Southport twenty years ago.

It was not without fear and misgiving on the part of some of its more prominent members that the Association visited Southport in 1883, but the success of the meeting in the northern watering-place was so conspicuous that at the final general meeting there was a unanimous expression of opinion that the Southport meeting of 1883 had been one of the most successful ever held, and a desire to repeat it at some future date. The meeting then stood sixth in point of numbers, and third in receipts. Since that date the Southport meeting has only been exceeded in numbers by the meetings in the neighbouring cities of Manchester and Liverpool, and in receipts by Manchester alone. 2714 people attended the meeting of 1883, and it is confidently hoped that this number will be exceeded in 1903.

The Corporation of Southport is working with the local committee to make the meeting a success, and has placed at its disposal the handsome suite of Municipal Buildings for use during the week of the Association's visit. These buildings include the Town Hall, Cambridge Hall, Art Gallery, and Victoria Science and Art Schools. The three first named of these were in use at the former Southport meeting of the British Association, but they were then without direct communication one with another. They are now connected by corridor bridges, and form an admirable suite of rooms for municipal and other social functions. The Victoria Science and Art Schools occupy a site behind the Cambridge Hall, with which, as well as with the Art Gallery, they are connected on the first floor, thus forming a further addition to the suite of reception rooms. This block of Municipal Buildings, which stands directly in the centre of the town, facing Lord Street, will be the headquarters of the Association. The reception room will be situated in the Examination Hall of the Science and Art Schools, the entrance being by the main doorway of Cambridge Hall. It is proposed that the Examination Hall shall be used for counter business only, the large room of the Art Gallery close by being used as a second reception room for conversational and general purposes. Two other of the picture galleries will be set apart for reading and writing rooms, whilst a fourth will be allotted to the representatives of the Press.

Three of the sections will meet in the Science and Art Schools, viz. Sections A (which is in two departments, Mathematics and Astronomy), B (Chemistry), and G (Engineering). Section L (Education) will meet in the Cambridge Hall, and Section H (Anthropology) in the Town Hall. Five out of the ten sections meeting this year will thus be located in the Municipal Buildings, and in easy communication one with another.

The council of the Association will meet in the council chamber of the Town Hall, and here also the general committee and the council of recommendations will hold their meetings. Two of the Corporation committee rooms in the Town Hall have been set aside for the deliberations of the International Meteorological Committee, which is meeting in Southport at the same time as the British Association, and of which a notice has already appeared in NATURE (May 14).

The laboratory of the Science and Art Schools will be used as a meteorological museum, and for the reception of apparatus and specimens illustrative of papers communicated to the sections.

The remaining five sections are all located in buildings within three minutes' walk of the reception room. Sections D and E (Zoology and Geography) will meet in the Temperance Institute, London Street, Section C (Geology) in Hoghton Street Church schoolroom, Section K (Botany) in Chapel Street Church schoolroom, and Section F (Economics), in the Y.M.C.A. building, Eastbank Street. The conference of delegates of corresponding societies will have two rooms placed at its disposal in Chapel Street Schools. All these buildings lie close to one another, and are easily reached by trams from all parts of the town.

The first general meeting of the Association will be held on Wednesday evening, September 9, at 8.30, in the Opera House, when the president, Sir Norman Lockyer, will deliver his inaugural address.

The Friday evening discourse will be delivered by Dr. Robert Munro, on "Man as Artist and Sportsman in the Palæolithic Period." On Monday evening a discourse will be given by Dr. Arthur Rowe on "The Old Chalk Sea, and some of its Teachings." The Saturday evening lecture to working men will be given by Dr. J. S. Flett, his subject being the recent volcanic eruptions in the West Indies. All these three lectures will be delivered in the Cambridge Hall, which seats about 1500 persons.

On Thursday evening the Mayor of Southport (Mr. T. T. L. Scarisbrick) will give a reception in the Municipal Buildings, and the local committee will give a conversazione in the same place on September 15.

The Mayor will further give a garden party in Hesketh Park on Friday afternoon, and Sir George Pilkington gives a garden party to a limited number of members at his residence, Belle Vue, on the afternoon of Monday or Tuesday, September 14 or 15.

The sections will not meet on Saturday, September 12, that day being set apart for excursions. Six whole-day and two half-day excursions have been arranged, and provision has been made in all for about a thousand persons. The excursions will be to (1) Manchester, visiting the works of the British Westinghouse Electrical and Manufacturing Company at Old Trafford. Opportunity will also be given of inspecting the new Technical School, the John Rylands Library, and the Chetham Hospital; (2) Stonyhurst College and Whalley; (3) Ribchester and Hoghton Tower; (4) Windermere; (5) Chester; (6) The Wirral Peninsula. Specially prepared pamphlets will be issued as guides to the excursions. The Westinghouse Co. has kindly promised to entertain the Manchester party to luncheon, and similar hospitality has been offered by the authorities at Stonyhurst College and by the Chester Society of Natural Science, Literature, and Art at Chester. The afternoon excursions on Saturday comprise drives to Hoole (the scene of the labours of Jeremiah Horrocks, the astronomer), Rufford Old Hall, and the ancient churches of Ormskirk and Halsall.

On the concluding day of the meeting, Wednesday, September 16, the following unofficial excursions have been arranged for the afternoon:—(1) Port Sunlight, Cheshire, Messrs. Lever's model village and soap works; (2) the Diamond Match Works at Seaforth, Liverpool; (3) the Cunard s.s. *Lucania* at Liverpool. On the Thursday following the meeting, opportunity will be afforded of visiting the Prescot Watch Works (a revived Lancashire industry), the British Insulated Wire Co.'s works at Prescot, the Lancashire and Yorkshire Railway Co.'s works at Horwich, and two collieries at Wigan. It has also been arranged for a steamer to run to Llandudno on this day.

Southport has made rapid advances in every direction during the last twenty years. Since 1883 much of the town has been rebuilt, the promenade has been widened, the marine parks and lake constructed, and many other important works of improvement have been effected. The Municipality of Southport is in the forefront of local government, and to its enterprise is in a large measure due the remarkable development of the town in recent years. Lord Street, the principal thoroughfare of the town, is a magnificent boulevard a mile long and more than eighty yards wide, with broad footways bordered by trees, suggesting comparison with the streets of continental rather than with those of English cities. The Municipal Gardens in Lord Street, in front of the Town Hall and Cambridge Hall, have become since last year, especially for visitors, the centre of life and movement in the town. Here the Corporation Military Band plays two or three times daily, and at night the trees are lit up with thousands of electric lights, the effect being striking and unique.

A handbook, or guide to the district, is being prepared, a copy of which will be presented to each member attending the meeting. The book will be illustrated and will contain specially prepared maps illustrating the topography and geology of the district. The district, roughly speaking, is that portion of south-west Lancashire lying between the rivers Ribble and Mersey.

The following subjects will be dealt with in the handbook:—"Sketch of the History of Southport"; "Meteorology," by Mr. Joseph Baxendell, Borough Meteorologist; "Health," by Dr. J. J. Weaver, Medical Officer of Health; "Geology and Physical Features of the District," by Mr. E. Dickson and Mr. H. Brodrick; "Botany," by Mr. Henry Ball and Mr. W. H. Stansfield; "Marine Zoology," by Prof. W. A. Herdman, F.R.S., and Mr. Isaac C. Thompson; "Coleoptera," by Dr. G. W. Chaster and Mr. E. Burgess Sopp; "Mollusca," by Dr. G. W. Chaster; "Mosses," by Dr. J. A. Wheldon; and "Antiquities," by Mr. W. Brunt. Mr. G. Napier Clark is contributing a chapter on Jeremiah Horrocks, the astronomer, and his connection with the district. The scientific portion of the handbook is being prepared under the direction of the Southport Society of Natural Science, and the general editors are Dr. G. W. Chaster, Mr. Geo. E. Johnson, and Mr. F. H. Cheetham.

In connection with the meeting and with the excursions, the following notes on the Southport district will be of interest. For the paragraph dealing with geology I am indebted to Mr. Harold Brodrick, for those on botany to Mr. Henry Ball, and for those on zoology to Mr. Isaac C. Thompson.

Geology.—The geology of the Southport district has for the most part to do with the Glacial and post-Glacial deposits. Of the older formations only comparatively small areas are exposed, having been entirely covered by Glacial deposits which have only in few places been denuded to the underlying strata. In the neighbourhood of Parbold, some ten miles inland, is a good exposure of Millstone Grit, while the Coal-measures may be well seen about Wigan, the Wigan coalfields being some of the most productive in England. Two small sections of the Permian rocks, with a thin stratum of a true magnesian limestone, may be examined in the beds of two small streams near Parbold. These beds have been proved to be fossiliferous, but only slightly so, not more than a dozen fossils in all having been found in them. Underlying the Boulder-clay, within eight miles of the coast and exposed in several places, are considerable deposits of the Keuper and Bunter divisions of the Trias.

In probably no part of England can that combination of clay, sand and gravel known as the Glacial Drift be better studied than in this district. Overlying the older formations, in some cases to a depth of more than one hundred feet, the Boulder-clay has suffered both denudation and erosion. By the latter action a range of prehistoric sand-dunes has been formed several miles inland of the present coast. These dunes offer several exceedingly interesting problems, and papers will be read before the Geological Section on this subject. Further inland, near Tarleton, are several large deposits of Glacial sand and gravel containing a considerable number of shells of an arctic type.

The Boulder-clay itself is of great interest, containing, as it does, boulders of Silurian Grits and Carboniferous Limestone from north Lancashire, Eskdale and Buttermere granites, and also several local granites and grits from the south-west of Scotland. These clays also contain a large number of Foraminifera, mostly of an arctic type.

A very large area is covered by peat mosses which have formed in the beds of old lakes and also covered the surrounding districts. These peat mosses in places are twenty feet in depth, and in them many canoes hollowed out of single tree trunks have been found. One of these, 17 feet long, will be on view during the visit of the Association.

The coast is fringed with a line of sand-dunes for a distance of some fifteen miles, while the whole of Southport is built on ground formerly covered with dunes, which have been levelled; in some places, as near Formby, six miles south of Southport, these dunes are more than three miles in width and rise to a height of more than 80 feet. The sand of the dunes is composed of materials eroded from the Triassic sandstones and then cast on to the shore by the sea, from where it is blown into dunes by the prevailing westerly winds. A considerable area in the estuary of the Ribble to the north of Southport is covered by a salt marsh formed by the deposition of silt at the meeting of the waters of

the Ribble with those of the sea. This district is of considerable interest, as in it may be studied the question of the formation of estuarian clays and their attendant flora and fauna.

On the whole, although at first sight the district does not seem to offer many opportunities of study to the geologist, yet on further consideration many problems and objects of great interest are to be found.

Botany.—Turning to the flora of the district, we find that, in spite of the apparent bareness of the long stretch of sand-dunes, they are by no means barren from a collector's point of view. In addition to the usual littoral flora, which is even here thoroughly representative in variety, nature, and outline, the diligent seeker will be rewarded by many choice finds. We must be pardoned for placing as an easy first, in regard to beauty as well as variety, the seaside form of the round-leaved winter-green, *Pyrola rotundifolia*, Linn., var. *maritima*, Kenyon. This plant is here abundant, and when in full bloom is an object of great loveliness. Here also, nearer to the sea line, may easily be found quite a family group of the centaurys (locally termed sanctuary). Every species now recorded in the London catalogue, save one, has been gathered on this coast. The rarest of them, however, the broad-leaved centaury, *Erythraea latifolia*, though originally found here, seems to be now extinct. Accompanying these plants there occurs, sometimes in patches like small fields, another member of the same natural order (Gentianeæ), the yellow-wort, *Blackstonia perfoliata*, Hudson, whilst in similar patches, and even more luxuriantly, there grows the Grass of Parnassus, *Parnassia palustris*, Linn. In higher and drier situations, too, the searcher is rewarded by the discovery, in fairly large quantities, of two beautiful euphorbias, both comparatively rare elsewhere, namely, *Euphorbia Paralias*, Linn., and *E. Portlandica*, Linn. The latter is a lovely object in the autumn, its green foliage changing to a bright crimson as the plant gradually fades.

The aquatic plants of the district are well worthy serious study, and include a very interesting group of drop-worts (Œnanthe), marestail, *Hippuris vulgaris*, Linn., and a few miles inland whole dykes covered over with the beautiful water-violet, *Hottonia palustris*, Linn. To refer once more to the sand-dunes, the collector may be interested to know that here grows that wonderful botanical enigma, the yellow bird's nest, *Hypopitys Monotropa*, Crantz, and a capital variety of orchids, including *Epipactis palustris*, Crantz. On the whole, to anyone in search of British wild flowers, the district is rich and repaying.

Zoology.—With the exception of its marine fauna, which is very rich, and is to be specially dealt with in the handbook now in preparation, Southport cannot be said to possess any very distinctive zoological features. No quadrupeds are peculiar to the district. But in early times, probably succeeding the last Glacial epoch, when the flat country around Southport was more elevated than now, it is evident that the Irish elk, *Cervus megaceros*, roamed here in abundance, many skulls and other remains of this animal having been found embedded in the clay beds of a large inland lake no longer existing, known as Martin Mere. It is suggested by Mr. G. W. Lamplugh, in his recent geological survey of the Isle of Man, that the Irish elk migrated across the waning ice-sheet which lingered in the Irish Sea at the close of the Glacial period.

In ornithology Southport bears a good record, and though the number must have been decreased of late years, no less than 130 species of birds were known to the district half a century ago. Among the birds that now visit the neighbourhood during spring and summer are the swallow, stone-chat, white-throat, yellow wagtail, northern diver, snow bunting, black and little tern, and wheatear, for many of which the numerous sandhills offer congenial attractions. In winter the bodies of storm-tossed birds, as the puffin, razor-bill, and stormy petrel, are often cast upon the shore, or become entangled in the fishermen's nets.

Numerous lizards haunt the sandhills, where also the conchologist will reap a good harvest not only in land mollusca, which are very abundant, but in marine species, including some of which no representatives are now found on the shore, and which were, doubtless, deposited at a distant era when the sea covered much of the present land. Cockles and shrimps are yet taken at Southport in great abundance. To the entomologist the sandhills of Southport afford a valuable hunting ground, as will be seen from the number of species and genera recorded in the forthcoming handbook.

Archaeology.—The district of Southport is not so destitute of interest to the antiquarian as might at first be supposed. Southport itself can boast no history prior to the end of the eighteenth century, but Birkdale and Churchtown, at the two extremes of the borough, can both claim a respectable antiquity. Roman coins are said to have been found on Birkdale Common.

This part of Lancashire is the "Inter Ripam et Mersham" of the Domesday Survey, but the antiquarian interest goes back to Roman times, when there were Roman stations on both the Mersey and Ribble, a Roman road leading from what is now Warrington through Wigan to Ribchester. The country west of the line of this road was, until comparatively recent times, very isolated, and consisted largely of low, swampy ground interspersed with woods and growing timber. The Roman station at Ribchester will receive the attention of the members of the British Association on one of the Saturday excursions, when Mr. John Garstang, of University College, Liverpool, and author of "Roman Ribchester," will explain the history of the Roman occupation on the site. Mr. Garstang will also read a paper on Roman Ribchester before Section H.

Close to Southport is the site of Martin Mere, once a large shallow fresh-water lake. It is now drained and used as agricultural land. Mention has already been made of a large canoe dug up here, and it is hoped that other antiquities (bronzes, &c.) obtained from the site of the lake may be on exhibition at the time of the meeting. Martin Mere is one of the many places which claim connection with the Arthurian legend. The river Douglas, the whole course of which lies within this district, is reported to be the scene of some of King Arthur's most bloody battles! Claims are also put forward by both the Ribble and Mersey, north and south of Southport, as the site of Athelstane's great victory of Brunanburg.

Lancashire is rich in old halls, and many of these are within easy reach of Southport. Visits will be paid to Rufford Old Hall, which contains a very fine example of a great hall of the fifteenth century, and to Hoghton Tower, an interesting and finely situated Elizabethan mansion, recently restored, the residence of Sir James de Hoghton, Bart. Hoghton Tower disputes with Pimp Hall, Essex, the title of being the house in which King James I. knighted the loin of beef. Of the lesser halls in the immediate vicinity of Southport, mention may be made of Lydiate, Hurleston, Mawdesley, and Heskin. Larger houses, like Speke and Smithells, lie further afield, and can only be visited by special permission.

In ancient ecclesiastical architecture Lancashire cannot be said to be well off. There is an ancient Norman chapel at Stydd, near Ribchester, an opportunity of visiting which will be given, but otherwise nearly all the churches of Lancashire belong to the late Per-

pendicular period. Halsall, however, four miles from Southport, possesses a fine parish church, largely of fifteenth century date, which will be visited, and the church at Ormskirk is unique in England in possessing a western tower and spire standing side by side. Sefton church is a late sixteenth century building, with remains of earlier work in parts, and has some good interior woodwork. At Burscough, eight miles distant, are the remains of an Augustinian priory, which in its day was one of the most considerable religious houses in Lancashire.

Carr House, at Hoole, a brick building erected in 1613, is reputed to be the house in which Jeremiah Horrocks observed the transit of Venus in 1639, and Hoole Church, though without architectural merit of any kind, is interesting as the chapel at which Horrocks officiated. There are the remains of a large number of wayside crosses in this part of Lancashire, an excellent specimen standing in Scarisbrick Park, about four miles from Southport.

Lathom is the scene of the famous siege of Lathom House by the Parliamentary forces in 1644, where Charlotte de la Tremouille, Countess of Derby, made her famous defence. She is buried along with the Earl in the neighbouring church of Ormskirk. Old Lathom House has given place to a classic mansion erected in 1724–34 from the designs of Leoni. Scarisbrick Hall is another old Lancashire mansion that has been rebuilt, the modern house, designed by Augustus Welby Pugin, being a fine example of the domestic work of the Gothic revival.

All along the coast of Lancashire are evidences of submerged lands, and the interest of the Leasowe coast of the Wirral Peninsula is well known to all those who have inquired into the subject of the alteration in the coast line of the country since Roman, or even Norman, times. An opportunity will be afforded of inspecting the submerged forest at Leasowe, and another submerged forest is to be seen nearer to Southport, at the mouth of the Alt, near Formby.

Of places not falling within the Southport district, but which will be visited by the Association, the antiquarian interest of Chester is too well known to need comment. At Whalley are the remains of a great Cistercian abbey, and Whalley church is a building full of architectural and antiquarian interest from the thirteenth to the sixteenth centuries. It contains the stalls belonging to the abbey church, which has completely disappeared. In the churchyard are three pre-Norman crosses. Time may allow also of a visit to Mytton church and Little Mytton Hall, which lie between Whalley and Stonyhurst. Stonyhurst itself has some antiquarian interest, the original building being a fine Elizabethan house, now incorporated in the vast college buildings. At Manchester mention must be made of the fifteenth century Chetham Hospital and Library, adjoining the Cathedral.

The archæology of the immediate district of Southport may be described as of local rather than of general interest, but a reference to the volumes of proceedings of the Historic Society of Lancashire and Cheshire, and of the Lancashire and Cheshire Antiquarian Society, which will be found in the Southport Reference Library, will show that antiquarian research is very active in the two counties.

The railway companies will issue return tickets to Southport from the principal stations in the United Kingdom at a fare and a quarter on surrender of the usual voucher issued to members. The tickets will be available from September 8 to September 18 inclusive. The local railway companies will issue return tickets at a fare and a quarter to members during the meeting for short distance journeys. F. H. CHEETHAM.

NEW SERUM DEPARTMENT OF THE JENNER INSTITUTE.

UPON the invitation of Lord Lister and the governing body of the Jenner Institute of Preventive Medicine, a number of distinguished guests inspected, on Friday last, the new laboratories and stables which the institute has recently acquired at Queensberry Lodge, Elstree, Herts.

The removal from the former site at Sudbury, near Harrow, became necessary from the encroachment of the Great Central Railway, and the authorities of the institute were fortunate in acquiring a site which is eminently suitable for carrying on the work of the department. This work consists largely in the preparation and testing of antitoxins, such as diphtheria antitoxin, tetanus antitoxin, and antistreptococcic serum, and in carrying on research work in connection with these, and on questions of immunity.

Certain researches also in comparative pathology can be suitably conducted only under such conditions as exist in a department of this character.

The buildings are on the summit of a small hill, and are surrounded by about twenty-eight acres of meadow land, which is conveniently divided into small fields suitable for pasturing and exercising the horses and other animals, such as goats and sheep, which are used in connection with the work. Queensberry Lodge itself has been retained practically as it was when the estate was acquired by the institute, and is now used for the accommodation of the junior staff, administrative offices, &c. The bacteriologist-in-charge lives in a separate house. The laboratories, which have been built by the institute from designs by Mr. Paul Waterhouse, are of the most modern type, with papyrolith floors with rounded corners, white glazed adamant walls with a dado of white tiles, and large window space. They are warmed by open fireplaces. There is a good gas and water supply, and the buildings are lit by Welsbach incandescent gas burners. The main ideas in the arrangement of the departments have been to provide separate buildings and isolated rooms for carrying out the different processes for the production and testing of antitoxins, thus avoiding risk of contamination of the serum, and at the same time affording adequate laboratory accommodation for the prosecution of research work. In this connection it has been considered advisable to have several small laboratories for one or two workers where undisturbed work can be carried on rather than large laboratories capable of accommodating a number of workers.

The laboratories comprise:—

A Large Routine Laboratory.—This room is furnished with both side and roof lights, and is fitted with centre and side benches, fume chamber, &c. It is used for general chemical work, for the filtration of diphtheria toxins, for fitting up apparatus, and for such work as section-cutting and blow-pipe work.

Two Private Research Laboratories.—These rooms are well lighted with a north-east aspect. They are completely equipped as bacteriological laboratories, have low benches for microscopical work, and separate Hearson incubators, shelves for reagents, media, &c.

The Serum Laboratory.—The windows in this room are of ruby glass so as to ensure a non-actinic light. It is used for the filtration and storing of the various sera, and contains two large ice-safes for that purpose. It is fitted with a work bench which has connections with a water-vacuum pump, and is also furnished with a Geryk pump.

The Engine Room is fitted with a gas engine driving a large Runne's centrifugal machine and a disintegrator. There is also a Root's blower, which supplies sterile air to the bottling room. There is a water-pump supplying a vacuum and high-pressure air to the neighbouring rooms.

The Incubation Room is a small insulated room, the insulation being obtained by its having double walls, the space between which is packed with asbestos. It has two doors forming a small "air-lock" to prevent the inrush of cold air on opening the door. By means of a gas-stove and Roux regulator the temperature is maintained at body-heat. This room is used for the cultivation of the different microorganisms used in connection with the work of the establishment.

The Bottling Room is reserved entirely for filling the serum into flasks. The windows are of non-actinic ruby glass, and are air-tight. Before bottling is commenced the room is filled with formalin vapour, which is allowed to remain in the closed room all night. In the morning the formalin vapour is displaced by a current of cold air from the outside of the building, which is blown into the room by the Root's blower in the engine room. This air is sterilised before its entry by passage through a large filter of sterile cotton wool. The current of sterile air is maintained throughout the process of bottling, entering the room through the filter and passing out by an exit in the roof through a cotton-wool filter.

The Culture Medium and Sterilising Room.—This room is used for the preparation and sterilising of the media employed in the cultivation of the various microorganisms. It is fitted with autoclaves, steam sterilisers, thermostats, &c. This room communicates with the cultivation room by double doors, through which the flasks can be passed after inoculation, thus avoiding lowering the temperature of the hot room by repeatedly entering it.

The Glass Cleaning Room contains a dry-heat disinfector for sterilising the glass apparatus, and is fitted specially for the purpose of cleaning and sterilising glass apparatus.

An Isolated Laboratory stands entirely apart from any other building. It is used for the preparation, filtration, and precipitation of such things as tetanus toxin, &c., and for the examination of small animals.

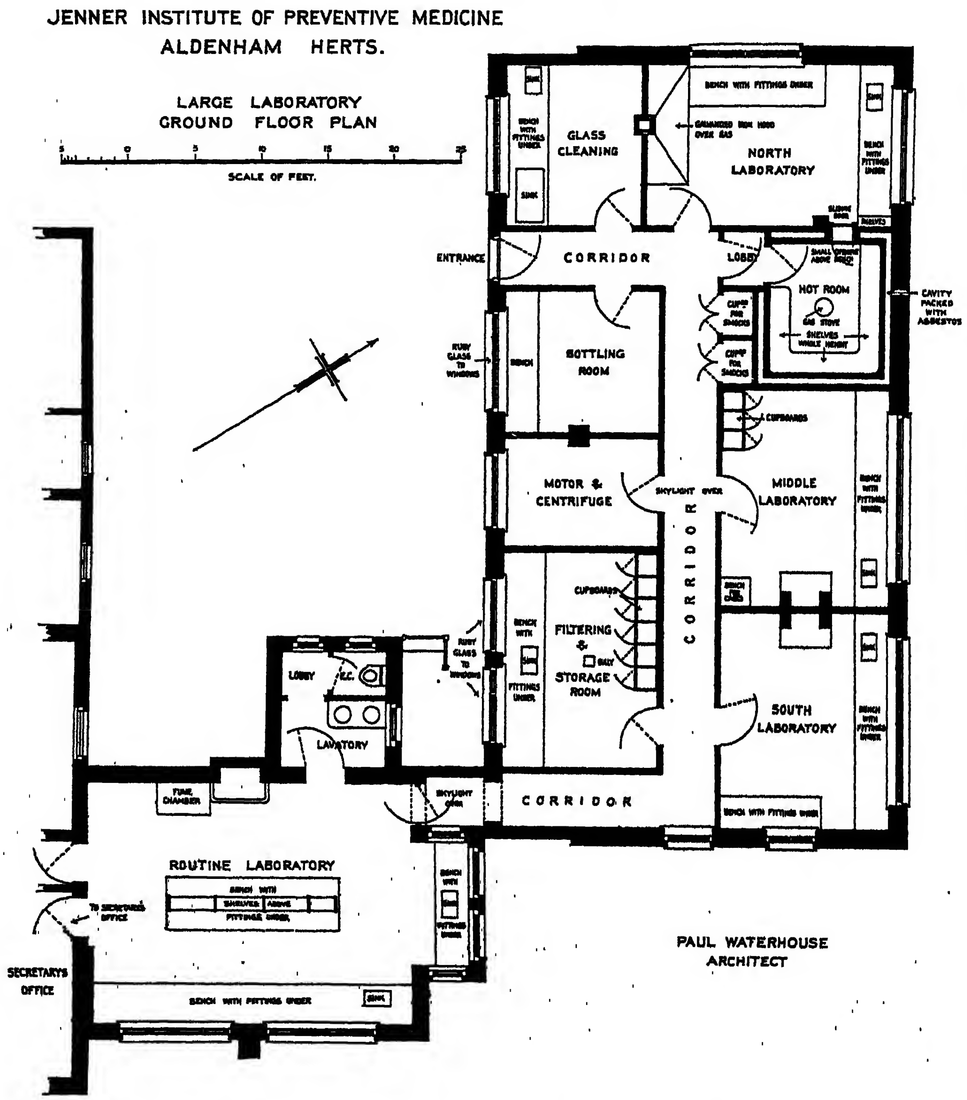

FIG. 1.—Plan of New Laboratories of the Jenner Institute at Elstree, Herts.

At a considerable distance from the main laboratories, there is a complete small department with stables for carrying on work in connection with other infectious diseases, in addition to those previously mentioned.

The Animal Houses are ordinary garden greenhouses which have been adapted and prove excellent for the purpose, as they are easily kept to an even temperature. The largest is used as an experimental animal house for the housing of animals employed in the testing of the sera, toxins, &c. The roof is covered with vines, which have been retained as affording a shelter from the sun in summer. The two smaller houses are used for breeding purposes. The three houses are heated by a system of hot water pipes.

The Principal Stables form two blocks of buildings about 200 yards from the laboratories. They are all brick, and of the most modern type. There are two yards, the first of which is covered by a high glass roof, and opening from this yard is the operating room, where the horses are injected and bled. The stabling consists entirely of loose boxes, which are very well ventilated, and are all of a large size, so that the animals have ample room to move about freely.

In the vicinity of the operating room is a small isolated room with slate benches, where the blood flasks are allowed to stand, and where the serum is decanted.

In one of the meadows, at a distance from the stables, is a loose box which is used as an isolation box. All new horses here undergo a period of quarantine. There are several other loose boxes in the various meadows, as well as an isolated cow-shed, goat-house, pigeon-house, rabbit-runs, &c.

ARCHÆOLOGICAL DISCOVERIES IN CRETE AND EGYPT.

THE undoubtedly close connection which existed between the Bronze age civilisations of Greece and Egypt is now generally recognised by archæologists. Not only was Egyptian influence on the development of the "Mycenæan" culture always very marked, especially from the period of the thirteenth Egyptian dynasty (B.C. 2000) to the end of the eighteenth (B.C. 1400), but the most recent discoveries seem to point to the unlooked-for conclusion that the two chief civilisations of the Eastern Mediterranean may have had a common origin, presumably in Africa. Certainly the further we go back the more striking are the parallels between early Egyptian and early Greek culture. It is, then, nowadays natural to group together the archæological discoveries which are being made in Egypt and in Crete, which was apparently the seat of the most fully developed phase of the Greek civilisation of the Bronze age.

During the present season (1903) Mr. A. J. Evans and Mr. Mackenzie have pursued the investigation of the great palace of Knossos in Crete, the legendary seat of the Minoan dominion over land and sea. The chief discoveries of the year are:—(1) a stepped theatre, after the fashion of that at Phaistos, but smaller and not so well preserved, lying to the west of the north gate; (2) a building, perhaps a small sanctuary, lying immediately north of the north gate, and directly in the line of its axis; (3) a house, lying a quarter of a mile to the north-east, on the slope of the hill, overlooking the stream of the Kairatos; and (4) two magnificent bronze vases, one of them closely resembling a type depicted among the offerings of the Keftian Cretans in the tomb of Rekhmara at Thebes in Egypt, *circa* 1550 B.C.

The house is remarkable, and contains a room with an apsidal end; it is, in fact, a sort of prototype of the basilica, which is now carried back to Mycenæan days!

What next year's excavations may bring forth it is impossible to guess, but there certainly seems no end to Knossos.

The Italian excavations at the small palace of Agia Triada, near Dibàki, in the Messarà, are proceeding under the direction of Prof. Halbherr and Drs. Pernier and Peribeni; the finds have been important, consisting of fragments of stone vases decorated with reliefs representing gladiatorial combats, bull-fights, and the presentation of spears to departing warriors by a king, and of a hoard of great talents of copper and bronze, measuring each more than a foot long, which are identical in type with the metal ingots brought as tribute to Egypt by the Keftians. The vases are of the same kind as that representing a harvest-home procession, found at Agia Triada last year.

The American and English excavations at Gourniă and Palaiokastro, under Miss Boyd and Mr. R. C. Bosanquet respectively, have produced interesting results, especially in the domain of pottery and small cult-objects, of which Palaiokastro and a hill-sanctuary in its vicinity have afforded numbers of interesting examples.

Apart from the discovery of the tomb of King Thothmes IV. by Mr. Carter at Thebes, and of a small portrait figure of King Khufu (Cheops), the builder of the Great Pyramid, by Prof. Petrie at Abydos, the most interesting excavations undertaken during the past season in Egypt have been those of Mr. Garstang at Beni Hasan. Below the well-known large tombs of the Twelfth Dynasty nomarchs, he has discovered a row of Sixth Dynasty sepulchres, and a great number of "pit-tombs," of the Eleventh and early Twelfth Dynasties. In some of these, notably in that of Nefer-i, a physician, has been discovered the funeral furniture intact. This, as is usually the case with burials of this period, included numbers of wooden models of the boats in which the mummies were ferried across the stream to the necropolis, and of the Nile-ships in ordinary use, with their crews, &c., notably a warship on which is a group of two men playing chess under a canopy, formed of two of the great cow-hide shields in use at the time; a similar shield-canopy is seen on a boat of the same period in the British Museum, No. 35293. Models of granaries and model groups of fellahîn engaged in their daily avocations were also found. Photographic records were taken of the various stages of the opening of all tombs, more than 450 negatives being secured. This is a most satisfactory feature of Mr. Garstang's excavations. It is also satisfactory to know that most of the finds will be placed in public museums and private collections in England. The results of the Cretan excavations have to remain in Crete, housed in a ramshackle Turkish *ex*-barrack, the floors, staircases, beams, and pillars of which are of wood, and in which smoking is freely permitted. The collections brought together there by the energy of English, American, and Italian excavators are unique, and include many classes of objects, *e.g.* the inscribed tablets from Knossos, which are unrepresented in the properly built and protected museums of Europe. It would, indeed, be deplorable if the treasures of Knossos, which have survived one conflagration—that in which the palace was destroyed—were to perish in another.

WHITE SPOT ON SATURN.

ON July 1, after observing Jupiter for some time, I directed my 10-inch reflector to Saturn, and found the details sharply defined. The dusky north polar cap was very distinct, and so was the dark belt on the north side of the equator. The belt was darkest and more strongly outlined on its southern side, probably by contrast with the bright equatorial zone. I soon noticed a large bright spot on the north side of the belt, and in a position nearing the western limb of the planet. It was followed by a diffused dusky marking. The luminous spot must have been on the planet's central meridian at about 14h. 1m., but this is only a rough estimate, as the marking was far past transit when I first saw it. It is to be hoped that this feature will prove fairly durable, in which case it may be expected to furnish an excellent means of redetermining the rotation period of Saturn.

A telegram from Kiel (mentioned in your last number) states that Barnard, of the Yerkes Observatory, saw a white spot in Saturn's N. hemisphere central on June 23, 15h. 47·8m. Williams Bay time. Allowing for the difference of longitude, this would be 21h. 42m. G.M.T. Adding eighteen rotations of Saturn of about 10h. 14m. will bring us to the time when the spot was approximately in transit as observed at Bristol, and there seems no doubt as to the identity of the objects.

This disturbance on Saturn will recall Prof. Asaph Hall's white spot seen in the winter of 1876–7, and followed from December 7 to January 2. A number of transits of this object were observed by Hall, Eastman, Newcomb, Edgecomb, and A. G. Clark, and from the data obtained the former found the rotation period of Saturn to be

10h. 14m. 23·8s. ± 2·30s. mean time.

The spot lengthened out into a bright belt, and soon lost its distinctive character.

Should the present object remain visible, it will be on or near the central meridian of Saturn on July 10, 13h., July 13, 12¾h., and July 16, 12h. 10m.

W. F. DENNING.

NOTES.

THE visit of President Loubet to England, as a guest of the British Court, is an event which should not pass unnoticed in the scientific world; he comes as the representative of the French nation. On many occasions President Loubet has shown interest in scientific meetings and congresses held in France, and has extended the warmest hospitality to the foreign members who attended them. His country takes a place in the foremost rank of those which are contributing to the advancement of science, and the names of leading French investigators are familiar words not only in the British Isles, but in all places where scientific knowledge is cultivated. It is a pity that the British associates and correspondants of the Academy of Sciences have not taken the opportunity to welcome President Loubet, as the representatives of the scientific interests of both nations. Such an act of simple courtesy ought not to have been omitted.

LORD KELVIN and Lord Lister have been elected honorary members of the Royal Society of New South Wales.

LORD LISTER has been admitted to the honorary freedom of the Merchant Taylors' Company in recognition of his "long and valuable services to the country, and particularly to surgery, by the discovery and application of the antiseptic treatment."

AT a meeting held last week in the rooms of the Royal Statistical Society, it was resolved to form a society for the promotion of scientific and philosophical studies in sociology. A committee was appointed to consider the question of the scope and aims of the society, and to draft a constitution to be submitted to a meeting in the autumn.

A PARIS correspondent writes:—On July 3 the *Temps* resolved to send a message round the world by telegraphy, using the Anglo-French system of transoceanic cables. The message was sent from Paris at 11 a.m., and consisted of the two words *Temps*, Paris, with the indication of the route, *viâ* Malta, Aden, Singapore, Brisbane, Vancouver, and French Atlantic Cable. As the indication of the route is not paid for, the cost of the experiment was only 13*s.* 1½*d.* No previous explanation or preliminary notice had been served to the several companies, but the organisation of the Anglo-French system is so perfect that the message arrived at the *Temps* office at 5.30 p.m. The time spent had been six hours for travelling about 40,000 miles, a measure of the commercial speed of electricity on the occasion of the inauguration of the American, Sandwich, Philippine, and Hong Kong system.

THE automobile races in Ireland last week give remarkable evidence of the power and perfection of modern motors. The race for the Gordon Bennett Cup, over a course of 370¾ miles, was won by a German car, driven by a Belgian, M. Jenatzy. The net time spent in covering this distance was 6h. 39m., which gives an average of nearly 56 miles per hour on ordinary roads. The second place was taken by a French car, the time being 6h. 50m. 40s. Three other competitors finished the race, two of them driving French cars, while the fifth place was taken by an English car. Some extraordinary speeds were attained by automobiles over a course in Phœnix Park, Dublin, on Saturday. For racing purposes the programme was divided into three sections, one for motor cycles, one for touring cars, and one for racing cars. The fastest motor cycle travelled at the rate of 48.2 miles an hour, and the fastest touring car at 46.5 miles an hour. In the racing section a Décauville light racer covered the course in 1m. 53 1-5s., at the rate of 62½ miles an hour; a 60-h.p. Mercédès at the rate of 78 miles an hour; a 70-h.p. Mors at the rate of 83 miles an hour, and also at 85.9 miles an hour.

REUTER'S Agency is informed that Commander Irizar, the Argentine naval officer who will command the relief expedition which is being sent out by the Argentine Government in search of Dr. Otto Nordenskjöld's South Polar Expedition, will leave for Buenos Ayres in a few weeks. The ship—the *Uruguay*—will be in charge of Argentine officers and crew, and will be provisioned for two years. It is not, however, probable that she will winter in the Antarctic.

THE eighty-sixth annual meeting of the Société helvétique des Sciences naturelles will be held at Locarno on September 2–5. At the same time and place the annual meetings will be held of the Swiss societies of geology, botany, zoology, and chemistry, and the Zurich Physical Society. In addition to the general and special meetings, there will be several receptions, banquets, and excursions to places of interest. The officers of the annual committee are M. A. Pioda, president, Prof. G. Mariani, vice-president, Dr. R. Natoli and M. C. Orelli, secretaries.

AN expedition recently left Baltimore for the purpose of making an exhaustive study of the Bahama Islands, and presenting reports upon them to the United States Government. We learn from the *Scientific American* that the expedition originated with Prof. George B. Shattuck, of the Johns Hopkins University, and is under the auspices of the Geographical Society of Baltimore, which defrays a portion of its expenses. Some of the principal lines of investigation will be concerned with the animal and plant life of the islands. The geology of the group will also be examined, and a bench mark will be left with the view of ascertaining to what extent, if any, the Bahamas are sinking or rising above sea level. The industries will be made the subject of a special chapter of the reports, as well as the physical condition of the inhabitants, the extent of the commerce of the principal towns, and any other economic features which may suggest themselves. An elaborate outfit of scientific apparatus for studying the meteorology and climatic conditions, for microscopic examination, and for photographic work has been provided. The diseases which may be prevalent and general sanitary conditions will be included in the investigation. This portion of the work will be in charge of Dr. Clement A. Penrose, of Baltimore, assistant director of the expedition.

IN NATURE of April 30 (vol. lxvii. p. 601) Prof. J. J. Thomson put forward the view that the energy of the Becquerel radiation given out by radio-active substances is produced by a change in the configuration of the atom. Dr. J. Stark writes from Göttingen to state that this view was suggested by him in his book "Die Elektrizität in Gasen" (Leipzig, 1902, p. 34), and later in the *Naturwissenschaftliche Rundschau* (January, 1903). Dr. Stark adds:—"As the transformation of atoms in some elements is still going on, it may be supposed that there was a time when our chemical atoms did not exist in the present amount, while other types of matter were more common. In the later change of the arrangement of the positive and negative electrons, or in the genesis of the present chemical atoms, a very large amount of the potential energy of their electrons was transformed to kinetic energy. The energy liberated in the change of chemical atoms is of a higher order of magnitude than that produced in known chemical reactions. Therefore it is reasonable to suppose that the temperature of the sun and stars is partly due to the genesis of chemical atoms."

THE prospect of active work in connection with the ship canal across the Isthmus of Panama has directed attention to the climate of the district, in which engineering work of exceptional difficulty will have to be undertaken. The results are generally reassuring, and with ordinary care a repetition of the horrors that accompanied the construction of the Panama railway need not be feared. The most noticeable feature in the temperature factor is its constancy throughout the year, the monthly range, in the mean, being confined between $78^{\circ}\cdot4$ and $80^{\circ}\cdot1$. The daily range on the coast is from 68° to 87°, and in the interior from 64° to 94°. It is easy to see the effect of the oceans in thus limiting the range of temperature, but necessarily there is an increase in the humidity, which is always high, throughout the year. There is a great difference in the rainfall on the Pacific and on the Atlantic coasts; about 140 inches may be anticipated on the former, while only half that amount will fall on the Atlantic side. From January to April the fall is very slight throughout the Isthmus, and therefore several successive months of dry weather can be counted upon, which cannot but be of great advantage in the engineering operations. Winds are always light, and give no trouble. Greater velocities than twenty miles an hour are rarely met with. The general health statistics are not unfavourable. Recent inquiries show that the mortality due to diseases of the climate has steadily diminished since 1881, while the percentage of deaths arising from European diseases has not increased. Of the total death rate, 91 per cent. is due to chronic organic diseases common to all countries, and only 9 per cent. is chargeable to local effects. This material improvement is due, in some measure, to the fact that the excavations have reached a level below the poisonous emanations of decaying organic matter, while, on the other hand, greater sanitary precautions have reduced the effects of the most deadly of the infectious diseases, yellow fever. Colon has been practically free from this scourge for some time, but improvements in Panama are loudly demanded.

IN the *Rendiconto* of the Naples Academy for April, Prof. Ernesto Pascal gives the integration of a differential equation of Riccati's form, but of a more general character than those previously considered. The right-hand side of Prof. Pascal's equation contains three constant coefficients, and the equations integrated by Malmstén, Brioschi, and Siacci are the particular cases deduced by putting one or other of these coefficients equal to zero.

VOL. v., No. 1, of the series of monograph supplements of the *Psychological Review* is a thesis by Dr. Joseph W. L. Jones on "Sociality and Sympathy." The author traces the development of consciousness to the point at which "consciousness of kind" emerges, and discusses the gradual evolution of social relationships and the rise of sympathy in any given race.

DR. COSTANTINO GORINI discusses in the Lombardy *Rendiconti* the remarkable power exhibited by the typhus bacillus of spreading along the surfaces of solids in contact with the nutrient liquid. This effect the author considers is due to the formation of filaments rather than to the mobility of the bacteria themselves, but it suggests the danger which may arise from watering food-plants with water containing the bacteria.

A REPORT on the dilatation of steel at high temperatures is given by MM. G. Charpy and L. Grenet in the *Bulletin de la Société d'Encouragement* for May. The most noticeable features brought out in the experiments were the sudden contraction at a temperature of about 700° common to carbon steels, the existence of a second point of contraction at about 300° in tempered steel containing 0·65 to 1 per cent. of carbon, and of a further point of contraction near 150° for tempered steels with more than 1 per cent. of carbon, and the absence of any observed relation between the dilatation-curves of nickel steel and their magnetic properties.

THE eleventh volume of the *Atti* of the Naples Academy of Physical and Mathematical Sciences contains a monograph by G. de Lorenzo and Carlo Riva on the crater of the Astroni, one of the most remarkable craters in the Phlegrean fields. It derives a melancholy interest from the fact that, before its completion, Signor Riva met with his death in the prime of life while ascending Monte Grigna from the Lake of Como. Another noteworthy feature is the monograph of 220 pages on the totality of prime numbers up to a given limit, by G. Torelli.

UNDER the title of "Bathymeter," Mr. Leonard Murphy describes in the *Economic Proceedings* of the Royal Dublin Society a simple apparatus for gauging the depth of liquids in wells and tanks. An air tube dips into the liquid to be measured, and an air compressor is connected both with this tube and with a reservoir of liquid into which there dips a gauge glass. On working the compressor the liquid in the gauge glass rises until the pressure is sufficient to force the air out at the bottom of the air tube, and the height of liquid in the gauge glass then indicates the height of liquid in the well above the end of the tube.

IN the *Annali di matematica pura ed applicata*, Signor T. Levi-Civita deals with singular solutions in the problem of three bodies or particles which attract each other according to the Newtonian law. The only case in which singular solutions occur is when, at some instant of the motion, two of the particles coincide; this involves an impact between the particles. The motion in which the particles are approaching impact is called by the author a trajectory of collision, the reversed motion being a trajectory of ejection. The case discussed is that in which the bodies are moving in one plane, and the mass of one is negligible compared with those of the other two.

FROM the *Economic Journal* we take the following table of the ages of German university professors in the year 1901, quoted from an article by Dr. F. Eulenburg in the *Jahrbücher für Nationaloekonomie*:—

Age	30	35	40	45	50	55
Number ... 2	23	124	206	256	262	
Age	60	65	70	75	80	85
Number ... 197	194	108	36	18	3	

where the upper figures represent ages, and the lower figures represent numbers of German professors in 1901 in the intervals between those ages. In 1890 the maximum number was between the ages of forty-six and fifty.

IN *Cosmos*, M. Lucien Fournier discusses the phenomenon recently described as the "flow of marble," which results in a gradual bending or deformation of marble blocks, as was described by Dr. T. J. J. See in a letter to NATURE of November 20, 1902 (vol. lxvii. p. 56). Among the theories proposed to account for the effect, the actions of sunshine and moisture have hitherto received support. M. Fournier now suggests another possible cause—elasticity. It is observed that blocks of granite frequently expand when they have been relieved from the pressure of the surrounding rocks in the process of quarrying. It is now suggested that a similar cause may account for the bending of the blocks of marble, and this explanation would account for deflections which assume a different direction from that which would be expected if heat and damp were the causes.

THE *Journal de Physique* contains two short papers by M. R. Blondlot on a new kind of light obtained originally after filtering the rays from a focus tube through aluminium or black paper. In studying the action of the radiations on an electric spark, they were shown to present the phenomena of rectilinear polarisation, and it was further found that both quartz and sugar produced rotatory effects. On passing the rays through a plate of mica, double refraction took place; finally, the existence of refraction was proved by concentrating the rays with a lens, and reflection was also observed. It followed that the radiations were entirely different from Röntgen rays, and must be attributable to a new kind of light. In the second paper in the July number, M. Blondlot finds that radiations possessing identical properties are obtained from an Auer lamp, and that the new rays will pass through certain metals and substances which are opaque to the radiations discovered by Prof. Rubens.

IN the *Proceedings* of the Royal Society for March, Mr. H. M. Macdonald, F.R.S., gave an investigation of the bending of electric waves round a spherical obstacle, which was suitable to explain Mr. Marconi's successes in employing wireless telegraphy over distances representing considerable arcs of the earth's circumference. Mr. Macdonald's solution has been called in question in papers communicated to the Royal Society by Lord Rayleigh and M. Poincaré. It is pointed out that Mr. Macdonald's conclusion as to the diffraction taking place without the production of any sensible shadow does not agree with the results known in the case of light; indeed, if the conclusion were accepted without any limitations, there would necessarily be daylight all night. From a mathematical point of view the results depend on the assumption that the spherical functions entering into the expression for the potential satisfy a condition of the form $dW/dr = ikW$; this is true in the case of spherical functions of low order, but unless the series for the potential is uniformly convergent, the solution may involve spherical functions of high order, for which the condition in question does not hold good.

WE have received from Prof. B. Sresnevsky a pamphlet containing synoptic tables of the daily rainfall values at all the meteorological stations of the Russian Baltic provinces for the year 1900.

THE *Transactions* of the South African Philosophical Society for April last contains a lengthy contribution by Mr. J. R. Sutton, superintendent of the De Beers meteorological station at Kenilworth, Kimberley, on the results of some experiments upon the rate of evaporation. For, as the author points out, of the dozens of patterns of evaporators, not one has hitherto been unreservedly accepted as a standard, and the results obtained from some of them show a rate of evaporation fully twice as great as others. The greatest mean annual result of seven years' observations by the author gives an evaporation of 90·11 inches, and was obtained from a copper pan about 5 inches deep and 8 inches in diameter, kept nearly full of water, and protected from the sun's rays. The monthly means varied from about 3 inches in June to nearly 12 inches in each of the months November and December. For the year 1900, the comparative annual values given by four evaporators are:—8-inch copper pan, 90·82 inches; a screened iron tub, enamelled white inside and out, 14 inches in diameter and 20 inches high, 61·98 inches; circular steel tank, nearly 4 feet in diameter and 30 inches deep, 55·21 inches; a Piche evaporating tube of the usual pattern, 82·83 inches. The author finds (1) that the most potent agency regulating the rate of evaporation was the humidity of the air; (2) that a wind factor is suggested; and (3) that the great perturbing influence attributed to the temperature of the water has not been exactly confirmed. The paper will well repay a careful study.

EVIDENCE of a connection between the occurrence of thunderstorms and the moon's age has been referred to in NATURE on several occasions. Prof. W. H. Pickering gives a table in *Popular Astronomy* to show the results of investigations of this relationship by various observers. From this table, which is abridged below, it will be seen that, with one exception, the number of thunderstorms occurring near the first two phases of the moon is greater than the number occurring near the last two.

The Moon's Phases and Thunderstorms.

Prof. Pickering adds:—"The number of observations here collected seems to be large enough to enable us to draw definite conclusions, without fear that further records will revise or neutralise them. From these observations we conclude that there really is a greater number of thunderstorms during the first half of the lunar month than during the last half, also that the liability to storms is greatest between new moon and the first quarter, and least between full moon and last quarter. Also we may add that while theoretically very interesting, the difference is not large enough to be of any practical consequence. Thus it would seem that, besides the tides and certain magnetic disturbances, there is a third influence that we must in future attribute to the moon."

FRESH evidence is continually coming to light to prove the artistic skill of the cave men of late Palæolithic times. M. E. Cartailhac has begun a memoir in *l'Anthropologie* (tome xiv. No. 2) on the stations at Bruniquel, on the banks of the Aveyron, which will add materially to our knowledge of these interesting people. Especially remarkable is an engraving, published by the same author (p. 179), of two bands of horses in alignment on a slab of stone from the main cave at Chaffaud, Vienne. This is the first example of regular grouping, and an indication of perspective in Palæolithic pictorial art.

THE shell-heaps of the Lower Fraser River, British Columbia, have been carefully investigated by Mr. Harlan I. Smith in connection with the Jesup North Pacific Expedition, and his results are now published, with numerous illustrations, in the *Memoirs* of the American Museum of Natural History, vol. iv. These shell-heaps seem to have certain peculiarities of their own; the objects found in them are more numerous and of higher artistic

value than those found in the coast shell-heaps, and skeletons are frequently found in the former and but rarely in the latter. It is probable that at an early time a migration took place from the interior to the coast and Vancouver Island. This migration carried the art of stone-chipping, pipes and decorative art to the coast. The culture of the ancient people who discarded the shells forming these heaps was in all essential particulars similar to that of the tribes at present inhabiting the same area, but it was under a much stronger influence from the interior than is found at the present time.

ARCHÆOLOGICAL excavations have been made by Lieut. L. Desplagnes in the tumuli of Killi, in the region of Goundam, in the neighbourhood of Timbuktu (*cf. l'Anthropologie*, tome xiv. p. 151). The mounds appear to have been the tombs of chiefs, along with whom were buried women and captives, and large quantities of offerings of various kinds. The originators of these funeral monuments surpassed the existing people of the district in the art of making varnished pottery and in the fabrication of bronze. The presence of marine shells shows that they had relation with maritime peoples, and other objects prove an extensive commerce. There appears to be some evidence that these unknown people were partly related to the Berbers, and that they were overwhelmed by the spread of Islamism in the eleventh century. The author thinks that perhaps certain isolated peoples whom he mentions may be the fugitive remnants of this formerly relatively advanced nation.

A MEMOIR on the geology of North Arran, South Bute, and the Cumbraes, with parts of Ayrshire and Kintyre, has just been issued by the Geological Survey. It is the work mainly of the late William Gunn, with contributions by Sir A. Geikie, Dr. Peach, and Mr. A. Harker, and is an explanation of Sheet 21 of the one-inch map of Scotland. A great variety of subjects is dealt with, as may be gathered from the lengthy table of formations represented, and there is much to justify the statement referred to by the authors, that the geology of Arran is an epitome of that of Scotland. The central granite mass forms the dominant feature, rising to 2866 feet at Goatfell, and it is bordered by the older metamorphic rocks, schists into which, as observed by Hutton more than a century ago, the granite has been intruded. Rocks probably of Arenig age, black schists, cherts and grits, similar to those of Ballantrae, and associated with old lavas and tuffs, have been discovered in the course of the survey. Notable additions have also been made to our knowledge of the volcanic rocks, and especially with respect to a huge volcanic vent, probably of Tertiary age, in which are preserved remnants of Rhætic, Liassic and Cretaceous formations, hitherto unrecognised in the region. Full particulars are given of the granite, and of the dykes and sills of felsite and quartz porphyry, pitchstone, and other rocks. The Old Red Sandstone and the Carboniferous rocks, the determination of the Triassic age of the newer red sandstones, conglomerates and marls, and the accounts of the Glacial phenomena and economic geology, furnish many topics of great interest. The memoir contains ten photographic plates, and is issued at the price of 4*s*.

THE additions to the Zoological Society's Gardens during the past week include a Pinche Monkey (*Midas oedipus*) from Colombia, presented by Mr. E. G. Percy; two Grey-headed Love-birds (*Agapornis cana*) from Madagascar, presented by Miss Luff; a Whistling Swan (*Cygnus columbianus*) from North America, presented by Dr. Cecil French; a Mexican Snake (*Coluber melanoleucus*) from Mexico, presented by Mr. W. G. Kershaw; two Whistling Swans (*Cygnus columbianus*), a Mocassin Snake (*Tropidonotus fasciatus*), a King Snake (*Coronella getula*), two Mexican Snakes (*Coluber melanoleucus*), a Seven-banded Snake (*Tropidonotus septemvittatus*), two Testaceous Snakes (*Zamenis flagelliformis*), a Striped Snake (*Tropidonotus ordinatus sirtalis*), a Long-nosed Snake (*Heterodon nasicus*) from North America, a Chained Snake (*Coluber catenifer*), a Couch's Snake (*Tropidonotus ordinatus couchi*) from California, a Horned Lizard (*Phrynosoma cornutum*) from Mexico, two Smooth Snakes (*Coronella austriaca*), an Ocellated Sand Skink (*Chalcides ocellatus*), European; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, a Common Rat Kangaroo (*Potorous tridactylus*), two Brush Bronze-winged Pigeons (*Phaps elegans*) from Australia, a Banded Aracari (*Pteroglossus torquatus*) from Central America, a Rat-tailed Opossum (*Didelphys nudicaudata*), a Salvin's Amazon (*Chrysotis salvini*) from South America, two Cutthroat Finches (*Amadina fasciata*) from West Africa, deposited; a Yak (*Poephagus grunniens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1903 *c*.—The following elements and ephemeris have been computed by M. G. Fayet, Paris, from observations made on June 22, 24, and 27, and published in *Circular* No. 60 of the Kiel Centralstelle:—

Elements.

T = 1903 *Aug.* 28·4715 (*M.T. Paris*).

$$\left.\begin{aligned}\omega &= 125^\circ\ 56'\ 53''\\ \Omega &= 293\ \ 38\ \ 40\\ i &= 84\ \ 6\ \ 48\end{aligned}\right\}1903\cdot0.$$

$$\log q = 9\cdot539534$$

Ephemeris 12*h*. (*M.T. Paris*).

1903	α h. m. s.	δ ° '	log Δ	Brightness
July 5	21 27 33	+12 10·9	9·6105	4·5
,, 9	21 6 46	+24 44·8	9·5213	7·6
,, 13	20 26 15	+38 57·9	9·4322	12·9
,, 17	18 53 22	+60 43·0	9·4424	14·1
,, 21	15 46 14	+68 40·8	9·4948	12·9

On July 13 the comet will, according to the above ephemeris, be about 7m. 20s. following, and 58'·9 south of γ Cygni, whilst on July 21 it will be seen in the constellation Draco a little more than one-third the distance from γ Ursæ Minoris to η Draconis on a straight line joining these two stars.

The above scale of brightness takes for its unit value the brightness at the time of discovery, and on June 25, when the value on this scale was about 1·4, M. Pidoux recorded that the comet was equal in brightness to an eighth magnitude star.

PENETRATIVE SOLAR RADIATIONS.—In a paper communicated to No. 24 of the *Comptes rendus*, M. R. Blondlot describes some simple experiments he has performed which appear to show that certain rays (which he calls "the *n* rays") emitted by the sun are capable of passing through various kinds of wood, metals, &c. He placed a fine glass tube containing a phosphorescent material, *e.g.* sulphide of calcium, in a darkened room in which there was a window exposed to the sun, but closed by means of an oaken shutter 15mm. thick, and then found that the phosphorescent material, which he had previously exposed for a very short time to feeble sunlight, continued to glow, but if a plate of lead were interposed between the shutter and the tube the phosphorescence became feebler, whilst it again increased when the lead was removed. Then an oaken joist 3cm. thick, a piece of cardboard, and several plates of aluminium were successively interposed, and the

phosphorescence emitted did *not* diminish, but a thin layer of pure water entirely arrested the *n* radiations. These radiations may be concentrated by a quartz lens, but are regularly reflected by a polished glass surface, whilst an unpolished glass surface diffuses them.

THE SPECTRA OF METALS AND GASES AT HIGH TEMPERATURES.—In No. 25, vol. xxxviii., of the *Proceedings* of the American Academy of Arts and Sciences, Prof. J. Trowbridge gives the details and results of an exhaustive series of experiments on the spectral phenomena observed when gases and metals are together subjected to high temperatures. Employing a large variety of conditions as to the temperature employed, the size of the capillary tubes and the materials from which they are made, and the distance and material of the poles, Prof. Trowbridge arrives at several interesting conclusions, all of which tend to show that in many cases the lines obtained are possibly due to products of the interactions between the gas, the poles, and the containing tube, which take place at high temperatures, rather than to the elements themselves. For instance, the metallic lines obtained from terminals placed 1cm. apart in rarefied air, or hydrogen, were reversed, the reversal coinciding in position with the line obtained in ordinary air, but the line was much broadened on the least refrangible side. The author suggests that this indicates the presence of a gaseous product, probably due to the oxidation or hydration of the poles. Again, when highly heated and rarefied hydrogen, or air, was passed through a tube of amorphous silicon or glass, broad bands, coinciding with the fainter silicon lines obtained under ordinary conditions, were produced, and Prof. Trowbridge believes that in the case of highly refractive metals, such as silicon, these bands are not really due to the metals themselves, but to the interaction between the metals and gases present.

The experiments showed that iron lines did not appear under what seemed to be favourable conditions, whilst aluminium lines did appear under these conditions. For this reason the author enters a *caveat* as to the care it is necessary to exercise when classifying stars solely from the variations in the appearances of their respective spectra.

ZENITH-TELESCOPE RESULTS.—In vol. ii. part i. of the *Publications* of the University of Pennsylvania (Series in Astronomy), Mr. C. L. Doolittle, director of the Flower Observatory, gives the results obtained from the observations made with the zenith-telescope during the period September 6, 1898, to August 30, 1901. After describing the corrections applied to the observed values, the report gives full details of each observation and its corrections, and then gives the values of the "aberration constant" determined during 1898–1899 and 1900–June, 1901, as $20''.540 \pm 0''.0103$ and $20''.561 \pm 0''.0085$ respectively. A curve and a set of tables, showing the variation of latitude at Philadelphia from October 1, 1896, to August 30, 1901, are also included in the report.

PHOTOMICROGRAPHY WITH A BROWNIE CAMERA.

THIS article does not put forth anything new in principle, but is the explanation of a simple method by which any student can, with little trouble and little expense, produce his own photographs of microscope objects, the idea being to direct attention to the inexpensiveness of the necessary apparatus.

The apparatus required includes only a small microscope and a light "fixed-focus" camera, and, of course, the necessaries for developing the negatives. The writer used a microscope of the rigid type generally regarded as little more than a toy, and worth only a very few shillings, and a Brownie Kodak. The instruments need practically no alterations to make them fit for use; the utmost that need be done is this:—Cut a piece of rather thick cardboard the same size as the front of the camera, and in the centre of it make a round hole to fit the eye-piece of the microscope. Glue this to the camera front.

In use the microscope is focused on object for distinct vision for a normal eye. If the experimenter be long- or short-sighted, then he must use appropriate spectacles.

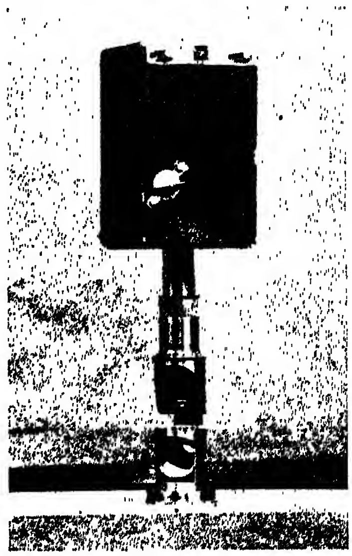

FIG. 1.

The light issuing from the eye-piece is thus rendered parallel, and if the camera be placed on the top of the eye-piece an image of the object will be in focus on the sensitive film. Of course, the optical axes of the camera and microscope must be parts of the same straight line, and the card glued to the camera is to assist the centring. The visual field is the exact area photographed.

Rhyolite. Olivine Diorite.

FIG. 2.

The exposure is made in the usual way, using the camera shutter. In the middle of a fine day exposures of from one to two minutes have been found ample, while in the evening ten or twenty minutes are necessary, using plates of the speed generally known as "Special Rapid." The Brownie camera is made for roll-films, but plates may be used thus:—The camera back is opened and a plate $2\frac{1}{4}'' \times 2\frac{1}{4}''$ laid on the frame over which the film is generally passed. On the back of the plate is placed a piece of black paper or thin card, and the back closed. This paper is necessary in order to exclude the light from the little red window, which is not non-actinic.

After exposure development is proceeded with in the ordinary way, using pyro-soda or any other developer the experimenter may prefer.

It will be seen from the specimens that the definition is, of course, not of the highest order, but considering the apparatus, one must not expect too much. The photo-

graphs are certainly more accurate than the student's sketches would be, and are probably made in less time. The lack of sharp focus at the edges is due to the cheap microscope used, and not to the camera, which is good enough for combination with any instrument likely to be employed in this manner. Any microscope and any similar camera may be used. The specimens reproduced show a magnification of ×20 diameters.

Considering the simplicity of the method and the slight cost of the apparatus, the idea should recommend itself to a good many students. W. MOSS.

SEISMOLOGICAL NOTES.

IN the nineteenth report of the Tokio Physico-mathematical Society Dr. F. Ōmori gives two short papers on the velocity with which earthquake waves are propagated. In calculating these velocities it is assumed that the paths followed are in all cases arcual, and that a correct velocity is arrived at by dividing the distance between Tokio and a station in Europe by the difference in time at which similar phases of movement were recorded at two such places. As to the soundness of this method, excepting as applied to the large waves of earthquakes, opinions vary. In another note by the same investigator, attention is drawn to the difference in the character of seismograms obtained at two stations about a mile apart. At one station, two distinct groups of maximum movements are shown. These are explained as the longitudinal and transverse components of elastic vibrations simultaneously produced at the seismic centre. At the other station the records are described as a series of maximum movements at fairly regular intervals. This feature is attributed to a rhythmic interference between the proper oscillation of a soft surface soil and the movements of an underlying harder ground. In a discussion on *pulsations* or small movements of non-seismic origin, it is shown that the period of these corresponds to the period of preliminary tremors, from which it is inferred that for both of these movements their periods depend upon the nature of the soil where they are observed.

The thirteenth number of the *Publications* of the Earthquake Committee (Tokio) consists of a series of papers also by Dr. F. Ōmori, several of which are identical with those to which we have just referred.

Long registers are given for the year 1900, the earthquakes in each of which originated in the same locality or at great distances from the observing stations in Tokio. In the earthquakes with distant origins, the periods of the preliminary tremors do not depend upon their duration, the duration of preliminary tremors being proportional to the distance such earthquake motion may have travelled. This is probably true for other phases of motion, and it has also been shown to exist for *macro-seismic* disturbances.

Other analyses relate to the relative magnitudes of earthquake movements, direction of first displacements, and matters of greater or less seismological interest.

In the *Bulletin* issued by the Philippine Weather Bureau for December, 1902, the Rev. Marcial Solá, S.J., gives an account of a violent earthquake which originated near Manila, and was recorded at many stations around the world. Materials from twenty-three of these stations are analysed, and the velocities with which waves were propagated through and round the world have been calculated. For the first waves, along chords corresponding to axes less than 46°, the velocity was 10·2km. per second., whilst for longer paths, up to 154°, this became 12·4km. per second. The maximum phase, travelling on arcs, did so with a velocity of 3·1km. per second, the lengths of the waves varying between 106 and 181km. Although these results fall closely in line with those of other observers, it may be pointed out that, if the time at which the earthquake originated was known, the values for velocities arrived at would be somewhat reduced.

In the last *Bolletino* (vol. viii. No. 8) issued by the Seismological Society of Italy, Dr. Giulio Grablovitz contributes a short paper describing a modified form of his *vasca sismica*. This is a circular tank about 1·5m. in diameter and 1m. in depth. On this there is a floating tray, the movement of which at the time of earthquakes is recorded upon a rotating cylinder. The chief feature in the records obtained from such a fluid pendulum, the period of which is short, is that the indicated amplitude of the preliminary tremors is usually more pronounced than that shown by other types of instruments.

Dr. G. Agamennone gives an account of the earthquake which, on June 29, 1896, originated in Cyprus, and was recorded at stations more than 3000km. from its centre. With the assumption that the wave paths were *arcual*, the first movements were propagated with speeds slightly exceeding 13km. per second. It may be pointed out that these values would be reduced had the wave paths been considered *chordal*. The remainder of the *Bolletino* is taken up with earthquake registers. These commenced in January, 1895, and have now reached June, 1901. Inasmuch as they do not simply refer to earthquakes noted in Italy, but to earthquakes which have spread over the whole world, for this class of earthquakes the Italian catalogue is for many purposes the most valuable which seismologists possess.

ETHNOGRAPHICAL STUDIES IN NORTH QUEENSLAND.[1]

THE student of folk tale, custom and belief will find in the last *Bulletin* issued by Dr. Walter E. Roth a mine of trustworthy data which will furnish new illustrations of the working of the mind of a primitive people. Though similar stories, ideas and habits may have been recorded previously by various observers in this and other parts of the world, yet none the less this record is of value as it confirms the older accounts in their broad aspects, and gives instructive variations in details. Some of the customs appear to be peculiar to the North Queensland natives, while others are definitely Australian in character. The information is given in those short, pithy paragraphs to which Dr. Roth has accustomed us; at times we could wish for more detailed information, but, on the other hand, we are spared any unnecessary verbiage, and there are no hypotheses or guesses. It is a comfort not to have to pick out facts from a mass of writing, and also to feel that the information can be absolutely trusted.

Readers of Spencer and Gillen's memorable book, "The Native Tribes of Central Australia," will remember that the Arunta do not recognise the relation between the sexual act and conception; this seemed so strange that it was felt that some confirmation of this ignorance was needed, and Dr. Roth now gives it to us, for he says that though the relation is not recognised among the Tully River blacks so far as they themselves are concerned, it is admitted as true for all animals—indeed, this idea confirms them in their belief of superiority over the brute creation. Dr. Roth offers the following explanation of this strange belief:—"When it is remembered that as a rule in all these northern tribes, a little girl may be given to and will live with her spouse as wife long before she reaches the stage of puberty—the relationship of which to fecundity is not recognised—the idea of conception not being necessarily due to sexual connection becomes partly intelligible." Various other beliefs and customs connected with sexual history are narrated, amongst which may be mentioned the seclusion of girls at puberty, at which period, as in the western islands of Torres Straits, as Dr. Seligmann has pointed out, the girls are half-buried and surrounded by a leafy bower.

Numerous magical practices are described; many have for their object the procuring of disease or death, others are curative, some induce success in love, while others give luck in hunting or fishing. A vital principle, breath, thought, will-power, soul, spirit, or whatever it may be termed, is recognised by all the tribes, but some deny this to animals and plants, while others will grant it to animals but not to plants. Dr. Roth's explanation of the opinion widely spread among the white men that the blackfellow believes he is transformed into a white man at death, or, as it is expressed, "black jump-up white-fellow," is that the vital principle, or spirit, of a native may be re-incarnated in a white man, and not that his body is actually transformed into that of a European. A number of illustrations further add to the value of this important publication.

A. C. H.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Allied Colonial Universities Conference is to be held at Burlington House to-day, July 9. Mr. James Bryce is to preside at the morning session, and Lord Strathcona and Mount Royal at the afternoon session. Official representatives have been appointed by the governing bodies of universities throughout the Empire to attend the conference. The universities of England and Wales, Scotland, and Ireland will be represented, and also fourteen Canadian universities, three Australian universities, New Zealand University, and the Cape of Good Hope University. Among the representatives appointed by colonial universities we notice the names of Prof. H. T. Bovey, F.R.S., Prof. E. Rutherford, F.R.S., Prof. J. G. MacGregor, F.R.S., Prof. R. Threlfall, F.R.S., Prof. Horace Lamb, F.R.S., and Prof. T. H. Beare. The following resolutions will be submitted:—(1) That in the opinion of this conference it is desirable that such relations should be established between the principal teaching universities of the Empire as will secure that special or local advantages for study, and in particular for post-graduate study and research, be made as accessible as possible to students from all parts of the King's dominions. Proposed by the Vice-Chancellor of Cambridge, seconded by the Vice-Chancellor of McGill University, Montreal, and supported by the principal of the University of London. (2) That a council, consisting in part of representatives of British and colonial universities, be appointed to promote the objects set out in the previous resolution, and that a committee be appointed to arrange for the constitution of the council. Proposed by the Pro-Vice-Chancellor of Oxford, seconded by Prof. R. Threlfall (representing the University of Sydney, New South Wales), and supported by the principal of the University of Birmingham. In addition to the abovenamed, Lord Kelvin, Sir Henry Roscoe, Prof. Rutherford, and several other representatives of universities have signified their intention of supporting the resolutions. Mr. R. B. Haldane, Sir Michael Foster, K.C.B., F.R.S., Sir Norman Lockyer, K.C.B., F.R.S., Mr. Fletcher Moulton, F.R.S., Prof. H. L. Callendar, F.R.S., Prof. J. A. Ewing, F.R.S., and Dr. H. P. Gurney (principal of the Durham College of Science) will also be among the speakers. A dinner will be held at the Hotel Cecil to-morrow evening, when the Prime Minister will occupy the chair.

IN an address delivered at a congregation of the University of Birmingham on Saturday last, the Chancellor, Mr. Chamberlain, described the progress and purpose of the university, and referred to the scheme for a postgraduate institute of applied science in London. In the course of his remarks Mr. Chamberlain said that, shortly after the idea of a university for Birmingham and district was put forward, the promoters found that much more than had originally been contemplated would be necessary to keep abreast of modern work and modern enterprise. Accordingly, a million of money was asked for instead of the quarter of a million originally contemplated. Up to the present time donations to the amount of something like 450,000*l.* have been received. Of that amount, 300,000*l.* are being spent in the first buildings of the new university. The City of Birmingham has voted a contribution equivalent to a halfpenny rate, which will provide an annual contribution which at the present time is between 6000*l.* and 7000*l.* a year. The county councils of Worcestershire and Staffordshire have contributed a present sum of 500*l.* per annum each. As to the purpose of the university, the view is perpetually borne in mind that it is to be a seat of all learning and an establishment for the promotion of original research. Every branch of learning which has its technical side will be separately represented by its own library, its own laboratory, and its own museum. The constitution of the university has undoubtedly given a stimulus to the higher education throughout the United Kingdom. Following the example of Birmingham, the colleges of Liverpool and Manchester, and also of Leeds, are developing themselves on the technical side, and are applying for independent charters as separate universities. And a scheme has been put forward for a technical college in London with similar objects to those of Birmingham University. When all these institutions are completed, there will be in our country, as there is already in Germany and in North America, a network of institutions all of which may help each other. These modern universities must of necessity be specialised to suit the conditions of the district in which they are established. May it not be, then, in the future that ideas, and even students, may be exchanged, and that many students, as in Germany already, may find their full course can only be completed by going from one university to another and seeking in each what it is best fitted to afford?

THE Lord Mayor of London laid the foundation stone of the new buildings of the University College of Sheffield on June 30. These buildings are part of a large scheme of extension and consolidation, and will cost more than 110,000*l.* The new metallurgical extension, containing new furnaces, is practically completed. The extensions for engineering, and new accommodation for electrical engineering, are in process of erection. The block for which the foundation has just been laid is situated on a site about three-quarters of a mile from the centre of the city, on the ridge of a hill, 420 feet above sea level, and adjoins the Weston Park on two sides. The general plan is that of buildings surrounding a quadrangle, with an annexe for the library. The buildings on three sides of the quadrangle are to be erected immediately, the fourth side hereafter when required. The building on the west side of the quadrangle, with a front to the park, is for the departments comprising arts, physics, biology, chemistry, law and commerce. That on the north side—also with a front to the park—contains accommodation for architecture, and the whole of the medical department, comprising anatomy, physiology, pathology, bacteriology, and public health, together with lecture rooms and medical library. It is expected that college work will be in full swing in the new buildings in October, 1905. As the result of an appeal that was made a short time ago for funds which would enable a University of Sheffield to be constituted, the sum of 51,400*l.* has been subscribed towards the new buildings, but it is understood that a further sum of 10,000*l.* is required to complete the portion now to be proceeded with, whilst 10,000*l.* will also be needed for the library, and about 10,000*l.* to complete the equipment of the various laboratories. It is desired to make adequate provision for, and to grant degrees in, the four following faculties:—(1) Arts, including education and commerce; (2) pure science; (3) medicine; and (4) applied science (engineering, metallurgy and mining). The City Council has pledged itself by a unanimous vote, in case university powers are obtained, to grant an annual sum not exceeding one penny in the pound out of the rates, equivalent to a capitalised sum of about 200,000*l.* To carry out the proposed university scheme in its entirety, a further annual income of 5000*l.* would be required.

AT University College, London, on Monday, Prof. E. H. Starling, F.R.S., Dean of the Faculty of Science, in his report of the work of the last session, referred to the scheme for the incorporation of the college into the University of London, and the suggested institute for advanced technical work. He remarked that certain conditions had to be fulfilled before the incorporation could take place—namely, the provision of new buildings for the clinical school and for the boys' school. The financial means to completely carry out these objects were still wanting. The college would need 40,000*l.* for the building of the clinical school and 60,000*l.* for the boys' school. Believing that money would be forthcoming for so essential a step in the provision of higher education for London, the council of the college and the university were cooperating in drawing up a Bill to enable incorporation to take place, and they hoped that the Bill would be introduced next session. It was proposed in the Bill to seek general powers for the incorporation of other institutions into the university. Only by incorporation of these interests into one, and by giving to the Senate of the university full control over the whole university teaching of London, could they hope to be strong enough to develop higher education and research in accordance with the growing needs of the time. This being their policy, it was with some apprehension that he had seen the publication of a scheme for creating a body, well equipped and endowed, within the university, but not belonging to the university. If the control of the new institution was secured to the university it would be certain to succeed, and they

need not trouble about the self-contradictory statements of the aims and the objects of the new institution with which they were favoured by enthusiastic amateurs.

A VACATION course in practical and clinical bacteriology will be held at King's College, London, commencing Wednesday, August 5, and ending Saturday, August 15. Names must be sent in as soon as possible to the secretary or to Prof. Hewlett.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 11.—"On the Propagation of Tremors over the Surface of an Elastic Solid." By Horace **Lamb**, F.R.S.

The paper treats of the propagation of vibrations over the surface of a "semi-infinite" isotropic elastic solid, *i.e.* a solid bounded only by a plane. For purposes of description, this plane is conceived as horizontal, and the solid as lying below it.

The vibrations are supposed due to an arbitrary application of force at a point. In the problem most fully discussed this force consists of an impulse applied normally to the surface; but some other cases, including that of an internal source of disturbance, are also considered. Owing to the complexity of the problem, attention is concentrated for the present on the vibrations as they manifest themselves at the free surface, and the modifications which the latter introduces into the character of the waves propagated into the interior are accordingly not examined minutely.

The investigation claims interest on theoretical grounds, and also in relation to the phenomena of earthquakes. Attempts to interpret seismic phenomena by the light of elastic theory have hitherto been based, for the most part, on the general laws of wave-propagation in an unlimited medium, as developed by Green and Stokes; but Lord Rayleigh's discovery of a special type of surface-waves has made it evident that the influence of the free surface in modifying the character of the vibrations is more definite, and more serious, than had been suspected. The present memoir seeks to take a further step in the adaptation of the theory to the actual conditions, by investigating cases of *forced* waves, and by abandoning the restriction to simple-harmonic vibrations.

It is found that the surface disturbance produced by a single impulse of short duration may be analysed roughly into two parts, which we may distinguish as the "minor tremor" and the "main shock," respectively. The minor tremor sets in at any place, with some abruptness, after an interval equal to the time which a wave of longitudinal displacement (in an unlimited medium) would take to traverse the distance from the source. Except for certain marked features at the inception, and again (to a lesser extent) at an epoch corresponding to that of direct arrival of transversal waves, it may be described, in general terms, as consisting of a long undulation leading up to the main shock, and dying out gradually after this has passed. Its time-scale is more and more protracted, and its amplitude more and more diminished, the greater the distance from the source. The main shock, on the other hand, is propagated as a solitary wave (with one maximum and one minimum, in both the horizontal and vertical displacements); its time-scale is constant, and its amplitude diminishes only in accordance with the usual law of annular divergence, so that its total energy, unlike that of the minor tremor, is maintained undiminished. Its velocity is that of free Rayleigh waves, and is accordingly somewhat less than that of waves of transversal displacement in an unlimited medium.

"A Method for the Investigation of Fossils by Serial Sections." By Prof. W. J. **Sollas**, F.R.S.

Mechanical difficulties preclude the study of fossils by serial thin slices, but serial polished surfaces may be obtained at any desired degree of proximity, and these, when the fossil and its matrix offer sufficient optical contrast, serve most of the purposes of thin slices. They may be photographed under the microscope, so as to furnish a trustworthy and permanent record. The sections may be used to obtain reconstructions of the fossil in wax. Several fossils have been successfully studied in this way, such as *Palaeospondylus Gunni, Ophiura Egertoni, Lapworthura Miltoni, Monograptus priodon,* and *Palaeodiscus ferox.* The sections are obtained at regular intervals, usually of 0·025mm., by means of an apparatus designed for the purpose by the Rev. F. Jervis-Smith, F.R.S., reader of mechanics in the university.

"An Account of the Devonian Fish, *Palaeospondylus Gunni,* Traquair." By Prof. W. J. **Sollas**, F.R.S., and Igerna B. J. **Sollas**.

June 18.—"Some Preliminary Observations on the Assimilation of Carbon Monoxide by Green Plants." By Prof. W. B. **Bottomley** and Mr. Herbert **Jackson**. Communicated by Prof. J. Reynolds Green, F.R.S.

"The Bionomics of *Convoluta roscoffensis.*" By Dr. F. W. **Gamble** and Frederick **Keeble**, M.A.

Convoluta is a minute green Turbellarian organism that lives in such prodigious numbers on the coast of Brittany as to cover long stretches of the beach with a thick green scum.

Previous observers have directed attention to the fact that Convoluta is not merely an animal, but is an association of an animal and a plant, or plant-like organism, which is represented by the green cells. These cells contain chlorophyll, perform photosynthesis, and store starch, but, unlike algal cells, they have no cell-wall, and they are believed to have no power of surviving the death of the animal tissue. Whether they are exceptional animal cells or infecting plant-cells, or algæ acquired in past time and now inherited, is unknown. But it is supposed that the life of the animal has been modified to suit their requirements, that from their reserves the animal is fed, and that to the renewal of these reserves its movements are directed.

The present paper is an attempt to gain further insight into this strange problem. Dealing first with the question of food, the authors show what rays of light are effective in producing a surplus of starch, but they believe that this reserve does not furnish the source of food on which the animal tissue of Convoluta is nourished; for not only does this starch disappear with extreme slowness (7–8 days) in darkness, but direct evidence is forthcoming that in all stages of development Convoluta can, and does, ingest, that in the earlier ones diatoms and algæ are normally ingested and digested, and that in the later stages the green cells are bodily aggregated and digested in the gut.

Passing to the development of the green cells, the authors find the first trace of these cells as colourless, nucleated structures in the gut of the recently hatched animal. Direct proof of the intrinsic or extrinsic origin of these colourless cells is still lacking. The indirect evidence, however, is strongly in favour of the latter mode of origin. On this view Convoluta makes a pure culture from a mixed infection.

Further analyses than heretofore of the effects of light, heat, gravity, and other agencies on the behaviour of Convoluta are given. The *tonic,* even more than the *tropic,* effect of light determines the periodic tidal movements, now to the surface of the sand, and now below the surface. The direct tropic effect of light is greatest in the green rays, absent in the blue, and reversed in the red. The effect is modified by the absorbing or scattering character of the background, and by the age of the animal. At the moment of hatching, Convoluta is aphototropic.

Geotropic response is not exhibited by those Convoluta which fail to develop their otolith. Normally it is shown from the moment of birth.

The paper concludes with a description of the daily and lunar variations in the size and behaviour of the colonies, and with an explanation of these variations in terms of the tropisms and other habits of Convoluta.

"The Spectra of Neon, Krypton, and Xenon." By E. C. C. **Baly**, Lecturer on Spectroscopy in University College, London.

The gases were illuminated by the passage of the discharge from an induction coil through them under reduced pressures. Vacuum tubes were filled with each one of them, and the glowing gas in a capillary portion was examined "end on" through a quartz window. Considerable difficulty was experienced in the use of the tubes, owing to the disintegration of the electrodes and the absorption of

the gas when the current was kept passing for long periods. The measurements were all made upon photographs taken with a Rowland concave grating of 10 feet focus and 14,438 lines to the inch; the first three orders of spectra were employed, and nearly all the chief lines were measured in two orders; the probable error of the measurements is less than 0·03 Ångström unit. Each gas gives bright-line spectra, krypton and xenon having two and neon one; the second spectra of krypton and xenon are produced by placing a Leyden jar and a spark gap in the circuit with the vacuum tube.

Physical Society, June 26.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Dr. **Waller** gave a demonstration of the effect of light on green leaves. The origin of these researches was the result of the consideration of the retinal effects after light stimulation, and the wish to have a sensitive surface naturally spread out for examination. The effect of light is to produce a current (of an E.M.F. of the order of 0·01 volt), at first from the illuminated to the dark parts in the leaf, and later (or as an after-effect) from dark to illuminated. These currents are apparently an index of two opposite processes in the leaf, *i.e.* dissimilation and assimilation, and give very close analogies to the analogous processes in animal tissues (*e.g.* nerves). Dr. Waller also demonstrated the "blaze" currents in animal and vegetable tissues. These are seen when a strong exciting current (such as an induction-shock of sufficient voltage) is led through a pair of non-polarisable electrodes, and these are then connected with a galvanometer. An electrical response (of greater energy than the exciting current) is given in a direction commonly homodrome to the latter, *i.e.* in the reverse direction to the ordinary polarisation counter-currents. This "blaze" response is the algebraic sum of post-anodic and post-kathodic currents; the resultant is commonly homodrome, but an antidrome blaze, distinguished from polarisation by its much greater order of magnitude, is also seen. Dr. Waller also showed two methods for the quantitative estimation of chloroform vapour in air. The first was by receiving the mixed gases into a flask of known capacity, absorbing the chloroform by means of olive oil, and reading the reduction of pressure by a manometer. The second was by the simple weighing of a light flask, first filled with air, then filled with mixed air and chloroform vapour.—Dr. N. H. **Alcock** exhibited a method of determining the temperature-limits of nerve activity in warm-blooded and cold-blooded animals. The higher limit was obtained by immersing the isolated nerve in 1·05 per cent. NaCl solution. It lies between 40° C. and 42° C. in the frog, 48° and 49° in the mammal, and is at 53° in the bird, corresponding closely to the coagulating point of the tissue proteids. The lower limits were obtained by cooling the nerve-chamber as a whole, and taking the temperature of the nerve with a compensated thermo-junction. The limits were −3°·5 C. for the frog, +3°·8 C. for the mammal, +6°·8 C. for the bird, giving a range of nerve-action of 45° C. to 46° C. for all animals. The method, therefore, permits of an hitherto impossible analysis of actually living nerve-substance.

Zoological Society, June 16.—Dr. F. Du Cane Godman, F.R.S., vice-president, in the chair.—Dr. H. **Woodward,** F.R.S., made a communication from Miss Dorothy M. A. Bate which contained a description of the remains of an extinct species of Genet from a Pleistocene cave-deposit in Cyprus, and which it was proposed to name *Genetta plesictoides*, sp. n.—Mr. G. A. **Boulenger,** F.R.S., described a new species of Gobiid fish from British New Guinea under the name of *Rhiacichthys novae-guineae*.—Mr. G. A. Boulenger also described the following five new species of reptiles from British New Guinea:—*Lygosoma milnense, L. granulatum, L. pulchrum, L. pratti,* and *Toxicocalamus stanleyanus*.—A second instalment of a paper, by Mr. Cyril **Crossland,** on the Polychæta of Zanzibar and British East Africa, contained descriptions of three new species of Marphysa, viz. *M. macintoshi, M. simplex,* and *M. furcellata*, and a new key to the known species of that genus. It also contained remarks on *Lysidice collaris* and its variations, and on the two species *Diopatra neapolitana* and *Onuphis holobranchiata*, which had hitherto not been met with in East Africa.—A communication on the parasites collected by the "Skeat Expedition" to Lower Siam and the Malay Peninsula in the year 1900 was read by the secretary on behalf of Mr. Arthur E. **Shipley.** The author stated that the area in which the collection was gathered had been hitherto unsearched by students of parasites, and referred to the high proportion of new forms that had been obtained. Among these were a new species of Tetrarhynchus, found in an Echinoderm, and an undeterminable species of Tetrarhynchus found in a sea-snake. The occurrence of these forms in such hosts was practically new to science. There were also described eight new species of Acanthocephala.—A communication from Messrs. Louis **Murbach** and Cresswell **Shearer** dealt with a collection of Medusæ from the coast of British Columbia and Alaska made in 1900. Specimens of fourteen species—of which five were new—were contained in the collection, and these were remarked upon or described.—Mr. F. E. **Beddard,** F.R.S., read a paper upon the modifications of the Syrinx in the Accipitres. The syringes of a number of genera were described in detail, and it was pointed out that the group could be divided into two families according to the form of this organ.

Chemical Society, June 17.—Prof. W. A. Tilden, F.R.S., in the chair.—The Longstaff medal was presented to Prof. W. J. Pope in recognition of his researches on the stereochemistry of compounds of elements other than carbon.—The following papers were read:—The estimation of arsenic in fuel, by Prof. T. E. **Thorpe,** F.R.S. A known quantity of the finely-powdered fuel is burnt in a stream of oxygen, the issuing gas is passed through a suitable absorption apparatus, and the absorption liquid, as well as the ash of the fuel, are tested for arsenic.—The electrolytic estimation of minute quantities of arsenic, more especially in brewing materials, by Prof. T. E. **Thorpe,** F.R.S. A special electrolytic arrangement is adopted whereby the electrolysis of dilute sulphuric acid is brought about in presence of the arsenical liquid, and the formation of arseniuretted hydrogen is detected in the usual way.—Crystallised ammonium sulphate and the position of ammonium in the alkali series, by Dr. A. E. H. **Tutton.** The molecular constants of crystals of ammonium sulphate indicate that the substitution of two ammonium groups for the two atoms of potassium in potassium sulphate produces approximately the same change as the substitution of two atoms of rubidium; on the other hand, the specific constants show that the ammonium radicle exerts a certain influence peculiar to itself in the series of alkali sulphates.—The action of hydrogen on sodium, by Mr. A. **Holt.**—The action of halogens on compounds containing the carbonyl group, by Dr. **Lapworth.** It is shown that the bromination of these compounds takes place more rapidly in presence of acids and alkalis.—Reactions involving the addition of hydrogen cyanide to carbon compounds, by Dr. **Lapworth.**—The acetoacetic ester synthesis, by Messrs. **Hann** and **Lapworth.**—Rimu resin, by Prof. **Easterfield** and Mr. **Aston.** This resin consists principally of rimuic acid $C_{18}H_{30}O_3$.—Note on the karaka fruit, by Messrs. **Easterfield** and **Aston.** This material, which in the raw state is bitter and poisonous, contains the glucosides karakin and corynocarpin. When an aqueous extract of the fruit is distilled, a distillate containing hydrocyanic acid is obtained.—The slow oxidation of methane at low temperatures, by Messrs. **Bone** and **Wheeler.**—The alkylation of sugars, by Prof. **Purdie** and Mr. **Irvine.**—Trimethyl-α-methylglucoside and trimethylglucose, by Messrs. **Purdie** and **Bridgett.**—Note on the corrosion of an Egyptian image, by Mr. H. **Bassett,** jun. An examination has been made of a green coating covering a bronze image, probably dating from the period 200–100 B.C., recently found in the delta of the Nile. The principal constituents are cupric chloride and oxide, lead oxide, stannic oxide, water, silica, and small quantities of nickel and iron oxides.—The oxidation of pinene with chromyl chloride, by Prof. **Henderson,** Messrs. **Gray** and **Smith.**—Some physical and chemical properties of strong nitric acid, by Messrs. **Veley** and **Manley.** It is shown that the density, contraction, refractive index, and electrical conductivity vary regularly until the concentration of the acid reaches 92 per cent., but from this point to 100 per cent. the variation is exceptional. These facts are in harmony with Hartley's view that acid of 96 per cent. strength contains a definite compound of the formula $3H_2N_2O_6,H_2NO_4$.—Notes on ozone, by Mr. **Inglis.** The molecular state of

ozone in acid and aqueous solutions cannot be ascertained by solubility determinations, since equilibrium between the gas and its solutions cannot be secured.

Geological Society, June 10.—Mr. J. J. Harris Teall, F.R.S., vice-president, in the chair.—On primary and secondary devitrification in glassy igneous rocks, part i., by Mr. John **Parkinson**. The types of primary devitrification as found at Obsidian Cliff are briefly reviewed, and reference is made to the conditions which favoured primary devitrification at Obsidian Cliff. After a brief reference to secondary devitrification, this part of the paper concludes with a summary in which the several relations of secondary to primary devitrification-structures are given.—Part ii., by Prof. T. G. **Bonney**, F.R.S. Certain conditions, such as slow cooling, supersaturation, and the presence of inclusions are favourable to crystallisation, some special cases of which are discussed in the paper. The structures thus formed in rocks may be classified as (1) the linear, and (2) the granular, and the former may be subdivided into (*a*) the rectilinear, (*b*) the curvilinear. Spherulitic structure in its simpler form falls under (*a*), and is at first little more than a radial grouping of molecules, the process becoming gradually more complicated. Of this, "graphic" or "pegmatitic" structure is a final stage, where two minerals are crystallising out of a solution, and one has slightly the advantage over the other, so that it virtually forms a skeleton-crystal. Into this the ordinary radial growth of a spherulite may be seen to pass; likewise also examples of (*a*) into those of (*b*), the latter being due to the "leading" mineral meeting with a rather stronger resistance, as if a crystal were forming in a very tough jelly. The granular structure is discussed, and explanations are offered of its varieties. In conclusion, the relation of some of these structures to an eutectic composition is discussed.—Geology of the Ashbourne and Buxton branch of the London and North-Western Railway—Crake Low to Parsley Hay, by Mr. H. H. **Arnold-Bemrose**. The present paper is a continuation of one published in 1899, and deals with the geology of the next eight miles of this railway.

Royal Microscopical Society, June 17.—Mr. Wm. Carruthers, F.R.S., vice-president, in the chair.—In the absence of Lord **Rayleigh**, his paper on the theory of optical images with special reference to the microscope was read by Dr. Hebb.—Dr. H. **Siedentopf** read a paper on the rendering visible of ultra-microscopic particles and of ultra-microscopic bacilli. The subject was illustrated by microscopes fitted with special illuminating apparatus, various objects, and drawings on the blackboard.—A communication relating to the preceding subject, sent by Dr. Johnstone Stoney, was read by the secretary. There was a lengthy discussion on the three papers, in which Prof. J. D. Everett, Dr. S. Czapski, Mr. J. W. Gordon, Mr. Rheinberg, Dr. C. V. Drysdale, Dr. Beilby, and Mr. Conrad Beck took part. Owing to the lateness of the hour, the following papers were taken as read:—On the "lag" in microscopic vision (continued); an improved horseshoe stage and a micrometric correction for minute objects, by Mr. E. M. **Nelson**; and a method of mounting bacteria from fluid media, by Mr. J. A. **Hill**.

Challenger Society, June 24.—Dr. R. N. Wolfenden in the chair.—Mr. V. H. **Blackman** contributed some notes on Bipolar plants; a comparison of the 259 Arctic and 269 Antarctic Algæ shows that no less than 54 species are found both north and south of the tropics, but not between them; of the larger brown seaweeds not even a genus is common to the two poles.—Dr. **Fowler** read notes on the distribution of some Amphipoda collected by him in the Bay of Biscay at various depths during a cruise in H.M.S. *Research*, 1900; they had been identified by the Rev. T. R. R. Stebbing. Among these were two Arctic cold-water forms, *Scina borealis*, Sars., and *Cyphocaris anonyx*, Boeck., taken between 750–500 fathoms and 300–400 fathoms respectively, but not known from shallow water at low latitudes; and *Hyperioides longipes*, Chevreux, distributed round the 100 fathom horizon as a centre, but not occurring at the surface or at great depths.

CAMBRIDGE.

Philosophical Society, May 18.—Dr. Baker, president, in the chair.—A coleopterous insect embedded in the wall of the human intestine, by Mr. D. **Sharp**, F.R.S. The author gave an account of the finding, by Dr. W. H. Ligertwood, of a living specimen of *Otiorhynchus tenebricosus* embedded in the wall of the intestine of a patient who died in the Wells Asylum. The position of the foreign body was in the ileum about eighteen inches from the ileo-cœcal valve. This beetle is purely herbivorous in its habits.—Exhibition of a rare parasite, by Mr. A. E. **Shipley**.—On the influence of electrons on colloidal solutions, by Mr. W. B. **Hardy**, F.R.S. Specially purified globulin from blood was dissolved (*a*) in a trace of acetic acid, (*b*) in a trace of sodium hydrate. In presence of acetic acid the globulin was found to move in an electric field from anode to kathode, in presence of alkali it moved from kathode to anode. In the former case, therefore, the globulin particles carried a positive charge, in the latter a negative charge. These two solutions were exposed to the radiations from radium bromide, and it was found that the electro-negative solution of globulin was turned into an opaque jelly in three minutes, while the electro-positive solution became more mobile and less opalescent.—On bismuth, by Mr. R. H. **Adie**. The discrepancies between the atomic weight of bismuth as determined by Schneider and Marignac = 208 and by Classen = 208·9, have been hitherto discussed on the assumption that the cause is the presence of lead. The author, by adopting a combination of fractionation as subnitrate and distillation as chloride, has succeeded in obtaining sufficient silica from pure bismuth to account for the low values of the former observers. The determination of the atomic weight and the isolation of a new coloured substance is now proceeding.—On the influence of great dilution on the absorption spectra of highly concentrated solutions of the nitrates and chlorides of didymium and erbium, by Mr. J. E. **Purvis**. The experiments prove that (1) the absorption bands of very highly concentrated solutions of the chlorides of didymium and erbium are not altered when the solutions are highly diluted. (2) The absorption bands of very highly concentrated solutions of the nitrates of didymium and erbium are considerably less diffuse when the solutions are highly diluted. This effect is analogous to that produced in the spectra of some gases and vapours by diminishing the density of the gas or vapour. (3) The absorption bands of very concentrated and very diluted solutions of the chlorides of didymium and erbium are precisely similar to those observed in the very diluted solutions of the nitrates of these two earths.—On a method of estimating the amounts of the oxides of didymium and erbium by means of the absorption bands of their solutions, by Mr. J. E. **Purvis**.—A lecture experiment to illustrate the rotation of a magnetic pole around a straight current, by Mr. P. V. **Bevan**.—Irreversible simultaneous linear reactions, by Mr. H. O. **Jones** and O. W. **Richardson**.

PARIS.

Academy of Sciences, June 29.—M. Albert Gaudry in the chair.—Researches on one and two fluid batteries, by M. **Berthelot**.—On the mechanical analysis of soils, by M. Th. **Schlœsing**. A discussion of the relation between the nature and amount of a substance deposited from suspension in water, and the time taken to settle. Experimental results on sandy, clay, and loam soils are given.—On the influence of the introduction of unsaturated radicles on the rotatory power of active molecules, α-allyl, α-propyl, and δ-methyl-β-cyclopentanonecarboxylic esters, by MM. A. **Haller** and M. **Desfontaines**. The conversion of an aliphatic active molecule into a cyclic molecule is accompanied with a large rise in the rotatory power. The rotatory power of the allyl ester is distinctly higher than that of the propyl derivative.—Observations on the comet 1903 *c*, discovered by M. Borrelly at the Observatory of Marseilles, June 21, by M. E. **Stephan**. The comet possesses a nucleus of the tenth magnitude, and a tail extending 5′ or 6′.—Observations made at the Observatory of Lyons during the partial eclipse of the moon of April 11; final results, by M. Ch. **André**.—Observation of the bright spot of Saturn with the 38cm. equatorial of the Observatory of Toulouse, by M. F. **Rossard**.—The elements of the Borrelly comet, by M. G. **Fayet**. Calculated from observations made at the Paris Observatory. The brightness of the comet will reach its maximum about July 14, and the comet will then be in a position very favourable for observation, and may be visible to the naked eye for some days.—Observ-

ations on the new Borrelly comet made at the Paris Observatory, by M. G. **Bigourdan.**—Observations on the Borrelly comet made with the 31·8cm. equatorial at the Observatory of Algiers, by MM. **Rambaud** and **Sy.**—Observations on the Borrelly comet made at the Paris Observatory, by M. **Salet.**—Observations on the comet 1903 *c* (Borrelly) made at the Observatory of Besançon, by M. P. **Chofardet.**—Observations on the Borrelly comet made with the Brunner 16cm. equatorial at the Observatory of Lyons, by MM. J. **Guillaume** and G. **Le Cadet.**—The influence of altitude on the duration of the reduction of the oxyhæmoglobin in man, by M. A. **Hénocque.** The effect of living at altitudes of 1000 to 2000 metres is to produce a marked prolongation in the duration of the reduction of the oxyhæmoglobin, a phenomenon which gives a new explanation of the adaptation of the human body to these heights.—On the integration of series, by M. W. H. **Young.**—On the experimental laws of sliding friction, by M. Henri **Chaumat.**—The electrotypograph and the teletypograph, by M. **de Tavernier.**—On the theory of nickel steels, by M. C. E. **Guillaume.** Nickel steels can be classified in two divisions, according as they do or do not possess a thermal hysteresis.—On the spontaneous dichroism of mixed liquids, by M. Georges **Meslin.** All liquids which possess spontaneous dichroism are also those which are the most active under the influence of the magnetic field; the reciprocal of this is also true.—On the phenomena connected with the mast in wireless telegraphy, by MM. André **Broca** and **Turchini.**—The relation between the dielectric cohesion of a gas and its temperature, by M. E. **Bouty.** For temperatures between 20° C. and 190° C., air, hydrogen and detonating gas possess a dielectric cohesion which is independent of the temperature, from which the law is deduced that the dielectric cohesion of a gas or of a mixture of gases depends only on the mean distance of the molecules.—Determination of the electrochemical equivalent of silver, by MM. **Pellat** and **Leduc.** A detailed account is given of the numerous precautions observed in this determination, the mean result being 0·011195.—On the electrolytic transport of certain ions in gelatin, by M. Aug. **Charpentier.**—The production of ozone in spirals with high tension currents of high frequency, by M. H. **Guilleminot.**—Positive accumulator plates of high capacity, by M. **Vaugeois.** Capacities of from 0·7 to 1·24 ampere-hours per square decimetre of plate have been obtained.—On recent results obtained in the treatment of arterial hypertension by d'Arsonvalisation, by M. A. **Moutier.**—A new method for putting in evidence ultra-microscopic objects, by MM. A. **Cotton** and H. **Mouton.**—On the anticipated liquefaction of oxygen from air, by M. Georges **Claude.** If air is liquefied progressively, the first portions are rich in oxygen.—Study of the mode of oxidation of manganese salts by alkaline persulphates in acid liquids, by M. H. **Baubigny.**—The preparation and properties of some new plumbic derivatives, together with their thermochemical data, by M. Albert **Colson.**—On an organic base containing phosphorus, its constitution and some of its salts, by M. P. **Lemoult.** The substance obtained by the interaction of PCl_5 and aniline has not the constitution $PCl(NH.C_6H_5)_4$ ascribed to it by Gilpin, but is more probably the hydrochloride of a new base, $(C_6H_5.NH)P.N.C_6H_5$, various salts of which are described.—The volumetric estimation of nitric nitrogen, by M. **Débourdeaux.**—On silicon amide and imide, by MM. Em. **Vigouroux** and **Hugot.** The amide is produced by the interaction of silicon tetrachloride and ammonia at temperatures below 0° C., above 0° the imide is the chief product.—Combinations of hydroferrocyanic acid with organic compounds, by MM. **Chrétien** and **Guinchant.**—The preparation of primary alcohols by means of the corresponding acids, by MM. L. **Bouveault** and G. **Blanc.** The methyl and ethyl ester of the fatty acid is reduced by sodium in the presence of absolute alcohol. Details are given for octanol.—The influence of the nature of the external medium on the formation and evolution of odoriferous compounds in plants, by MM. E. **Charabot** and A. **Hébert.**—New method for the estimation of oxalic acid in urine, food, &c., by M. **Albahary.**—On the production of glucose by animal tissues, by MM. **Cadéac** and **Maignon.**—Researches on the transversal scalariform striated bands in the cardiac fibres, by M. F. **Marceau.**—The action of carbon dioxide on the eggs of echinoderms, by M. C. **Viguier.** The theory of temporary poisoning of Delage is not true for the sea urchins; carbon dioxide is not clearly differentiated from other reagents used in experiments on artificial parthenogenesis.—On the development of the ovary of *Polyxenus lagurus*, by M. A. **Lécaillon.**—The action of emulsin on salicin and amygdalin. Theory of the action of emulsin, by MM. Victor **Henri** and S. **Lalou.** The emulsin forms an intermediate compound with the body upon which it is acting, and this is decomposed, regenerating the ferment.—On the teratological forms of *Sterigmatocystis nigra* deprived of potassium, by MM. **Molliard** and H. **Coupin.**—On *Cryptostegia madagascariensis*, by M. Henri **Jumelle.**—On a new group of fungi, the Bornetineæ, and on *Bornetina Corium* of the vine, by MM. L. **Mangin** and P. **Viala.**—On the bilateral symmetry of the rootlets of *Pontederia crassipes*, by M. **Chiffot.**—On the presence of macroscopic crystals of albite in the dolomites of the Trias of Crete, by M. L. **Cayeux.**—Observations on glacial phenomena in Corsica, by M. Paul **Castelnau.**—On the existence of two great circles of maximum seismic instability, by M. de Montessus **de Ballore.**—On a chicken which lived seven days after hatching out, with a second yolk enclosed in the abdomen, by M. Frédéric **Houssay.**—Apparatus for the inhalation of oxygen, by M. **Guglielminetti.**—The variable state of active muscles during the time of a contraction in the ergograph, by MM. A. **Imbert** and J. **Gagnière.**—Dust shower recently observed in Iceland, by M. Stanislas **Meunier.**

THE UNIVERSITY IN THE MODERN STATE.

IV.

IN previous articles we have pointed out that the penuriousness of our national policy towards the Universities results in the worst form of extravagance, the waste of thought and effort through want of proper tools. Because we will not give more, even what we do give is robbed of its proper fruit. Few institutions could be found which illustrate this more clearly than the three colleges of the University of Wales, in spite of the active work which they are doing.

The earliest of their charters is barely twenty years old, and the University was only founded in 1895, yet they have within their walls some 800 matriculated students pursuing full degree courses, and, roughly speaking, as many more who are either preparing for external degrees or diplomas, like the medical students at Cardiff; or taking some university courses as a part of a professional curriculum, like most of the normal and many of the theological students at all three colleges. The total population of Wales amounts to only 1,700,000, so that a total of some 1500 students makes a proportion of nearly 9 in 10,000, as against nearly 5 in England, nearly 8 in Germany, and nearly 13 in America (see our article of May 14). This is strong evidence of the eagerness with which university education is sought in the Principality, and of the confidence felt in its colleges. And the soundness of their teaching as a whole is indicated both by the names that appear on the list of their teachers and by the successes won by their former students at older Universities and elsewhere.

What, then, is their need to-day? Why can they not continue the work they have begun?

For two reasons. First, because their achievements so far have been attained at too great a cost. The beginning of a new and promising national movement aroused among its first promoters a spirit of enthusiasm and self-sacrifice which has not, indeed, passed away, but which has been sobered by bitter lessons. Those who knew anything of the life of the late Principal Viriamu Jones know that he was literally killed by the burden of too heavy a task; and there have been several other cases of serious overstrain, though none have ended so tragically.

From facts before us it is clear that not merely the principals, but the heads of all the large departments in the colleges, feel that the difficulty of meeting the growing duties of the university without any increase in its endowments has reached an intolerable degree, that is to say, from the outsider's standpoint, it has become incompatible with real efficiency.

In the second place, the cost of university education has risen greatly since the colleges began their work. The developments in education which have taken place in cities like Liverpool and Birmingham—to mention these alone—have created a new demand for men fitted for professorial work; and conditions which twenty years ago, when the work of the colleges was lighter than it is now—and when the Civil Service drew no men from the Universities—were sufficient to attract young men of distinction, no longer seem so desirable.

Nearly all the English colleges have been steadily forced by competition to raise the terms they offer to their staff. We know of two or three instances in which stipends have been specially raised in order to secure some professor who was at the time in the service of a Welsh college.

Even from an English point of view it is clear that this implies that larger funds will have to be found if university education is to be maintained at an efficient level. But in Wales, where it is impossible to raise such funds on any adequate scale, the facts wear a more serious aspect. The colleges feel their needs in three directions, in teaching, in research, and in administration; all alike are unnaturally burdened by poverty. In regard to teaching, perhaps the worst case is that of subjects like geology, botany and economics, which in more than one college are represented only by lecturers; their remuneration varies, but is at best scarcely more than half the professorial stipend. In all the colleges, changes of staff are undesirably frequent.

It seems unkind to point out further that large branches of knowledge like chemistry and engineering, or, on the "Arts" side, English or philosophy, not to mention older subjects, have outgrown the power of any one man to teach properly. This fact has been recognised by wealthier colleges (especially in Germany and America), in which each of these subjects employs several professors.

In Wales, again, the later developments of university study, such as the different branches of commerce, are hardly represented at all.

Finally, under this head, we may observe that in no one of the colleges is there any provision for pensioning their teachers when they reach the limits of effective work, and it is clear that this will shortly become a serious question.

In research we must acknowledge how much good work has been done—the names of Principal Viriamu Jones and Prof. Gray (now of Glasgow) at once suggest themselves in the department of physics alone; and among the present members of the colleges there are men of distinction both in science and letters. But the difficulties they have had to face have always been serious, and of late years have grown greater rather than less.

For want of adequate endowments both the laboratories and the libraries have grown steadily poorer in proportion to the growing demands of study. In one of the colleges the total expenditure on the library for more than twenty subjects, including the cost of periodicals and binding, is some 150*l.* a year! Everyone knows the discouraging effect of finding that some instrument or book of which one is in pressing need is out of reach.

The long vacation, it is true, offers opportunities, but here, again, a man's powers of research are limited by financial conditions. Men who are hard at work examining through most of July and August will not produce a great deal of original work in Septem-

ber, and the administrative work of the colleges now continually intrudes even upon the long vacation. From a general point of view, however, such disabilities of members of the staff would be of less consequence if the younger members of the colleges, honours students, or graduates of promise could secure more favourable conditions. Unfortunately, it is only too obvious that where a professor's chances of conducting original work are meagre, those of his students will, as a rule, be more meagre still. And in spite of the zeal with which the University of Wales has striven to foster original research, in every subject, in the regulations for its higher degrees, it is clear that unless the colleges can be placed in a better position financially, these efforts are doomed to disappointment. In one of the colleges a recent gift of valuable, if not unique apparatus is lying unused, and must do, until funds are found to build and maintain a proper laboratory to contain it.

Thirdly, and perhaps chiefly, the colleges suffer from their present position on their administrative side.

Making bricks without straw is not merely a discouraging, but an extremely difficult operation, and in any institution which attempts it, in the long run the best wits of its staff will be those that are set to the task. The colleges are finding more and more that even their teaching day is honeycombed with business.

Nor is this all. Where money is scarce, the spending of it is apt to be attended with an amount of ceremony which is itself a burden. In one college we are told it needs a series of resolutions discussed by four or five bodies before a new charwoman can be engaged. There could not be a better illustration of the waste of time which poverty entails. All the colleges serve some eight or nine masters in the shape of outside public bodies, who maintain different classes of students, and the necessity of explaining and justifying points of educational policy to so large a number of different popular authorities is a very serious task. At every turn it is necessary to consider not merely what is the right course, but what is the best form in which to secure its adoption. That under such conditions the colleges should have been able to do anything at all is satisfactory evidence not only of the keen interest in the university which is taken generally by the public bodies of Wales, but also of the wisdom with which the colleges, especially their principals, have discharged their task. Whatever may be thought of the policy of a democratic basis for university education, it will be admitted that the burden of the arrangements ought not to fall upon those who are also responsible for the solid work of teaching. In Wales this is largely the case, and both the teaching and the policy of the colleges are likely in the end to suffer.

In the second article of this series (March 12) we saw that the great bulk of the endowments of the German universities was provided by the State, 81 per cent. of the total being so provided in Prussia, and 74 per cent. in Germany as a whole. Wales, happily or unhappily, possesses comparatively few men whose individual possessions could enable them to take part in endowing her colleges in any way commensurate with the need. Of the sums that have been raised for buildings, a great part has been collected, at the cost of healthy but disproportionate effort, from the shillings and pence of artisans and small farmers or traders. It is not surprising, therefore, to find that the colleges and the university depend already mainly upon public funds. The County Council grants to Cardiff and Aberystwyth must in fairness be counted as fees, not endowments, since they are given in return for teaching a definite class of students, and a change of policy in the local authorities might at any time modify or even divert their contributions. The figures are approximately[1] as follows, reckoning the interest on investments, as heretofore, at 2½ per cent., and including in the Government grants those devoted to special objects, such as agriculture, and the training of primary teachers.

Present Endowment of University Education in Wales.

	Income from Private Endowments.	Income from Government Grants.
	£	£
University College, Aberystwyth...	375	6000
University College, Bangor	1225	6000
University College, Cardiff	750[2]	5250
The University of Wales ...	—	4000
Totals	£2350	£21,250
Percentages	10	90

There is only one conclusion. In great cities like Liverpool and Manchester there is accumulated wealth and an accumulated tradition of culture to which their colleges have appealed with some success. In Wales the culture has been for centuries remote from university life, and the wealth, as we have seen, is non-existent. If, therefore, the Government wishes that the 21,000*l.* a year which it now spends in grants to the colleges and the University of Wales shall not be wasted, it is high time that it should face the question of what they really need.

In order to represent these needs in as concrete a form as possible, we have made inquiries as to the sums which, in the opinion of responsible persons at each college, would suffice to place them in a position to discharge their work with real efficiency. In each case we shall mention two capital sums, the one that required to construct or complete the buildings and equipment of the college, the other that required as an endowment for maintenance, the interest in this latter case being reckoned at 2½ per cent. Aberystwyth has from the first been the most fortunate of the three colleges in the matter of buildings, so that its needs under this head are smaller; similarly Bangor needs slightly less towards maintenance as being possessed of somewhat larger invested endowments, Cardiff and Aberystwyth having only very small possessions of this kind; trust-funds for scholarships are, of course, disregarded altogether in the estimate.

The figures assume that the present Government grants will continue, and under both heads state the

1 The exact figures vary slightly from year to year.
2 Including the annual grant of 350*l.* from the Drapers' Company for Engineering.

sums needed in addition to all the resources the colleges at present possess.

Funds needed for University Education in Wales.

	A. For Buildings and equipment.	B For endowment.
	£	£
University College, Aberystwyth	99,800	1,071,500
University College, Bangor... ...	176,500	960,400
University College, Cardiff... ...	162,000	1,176,400
The University of Wales	—	288,400
Totals	£438,300	£3,496,700
Grand total	£3,935,000	

In round figures, therefore, we may say that university education in Wales needs an endowment of four millions sterling to secure its efficiency. This will not be thought an extravagant figure when it is remembered that the need of the Birmingham University was estimated at five millions, and that the Welsh colleges minister to the needs of a far more diverse population. The agriculture, the manufactures, the mining and the over-sea commerce of Wales all demand the enlightenment and intelligence which can only be developed in universities efficiently equipped for their work.

FORMOSA.

The Island of Formosa. By James W. Davidson, Consul of the United States for Formosa. Pp. 646+xxviii+46. (London and New York: Macmillan and Co., Ltd., 1903.) Price 25*s.* net.

CONSUL DAVIDSON'S work on Formosa is a heavy quarto volume of 700 pages, in which the liberal use of small type indicates that its author has tried to pack as much as possible within a given space.

It is not a lap book, but a book for the study table, in which 168 photographs and other pictures give of themselves a liberal education about things Formosan. A coloured frontispiece shows Mount Morrison capped with snow, 13,880 feet in height. This, which is one of the many peaks in the mountain ranges which form the backbone of Formosa, is the highest mountain in the Japanese Empire. Another illustration is that of sea cliffs on the eastern coast. These, which attain heights of 5000 to 6000 feet, are possibly the highest sea cliffs in the world. Orographic features with these magnitudes in an island about half the size of Scotland are certainly remarkable. From other pictures, in which are depicted generals, battles, dismantled forts, Chinese temples, the surrender of the Dutch to Koxinga, the torturing of Dutch by the Chinese, Japanese streets, tea houses and barracks, a Christian church, a police station, a meteorological observatory and railways, it may be inferred that, politically and socially, Formosa has had a chequered history.

The Chinese, who have known Formosa since A.D. 608, tell us that it was created by certain fierce dragons which glided out from the gates of Foochow, and lashed up the bed of the ocean until Formosa was created. The origin of this may rest on the fact that Formosa has, at least in part, resulted from volcanic activity, and in the Eastern mind such activities and dragons were in past ages closely associated. In the early Middle Ages the harbours of this island, which are almost entirely confined to its western shores, were used as clearing houses for trade between China and Japan, and also as homes for pirates. One princely freebooter who settled and married in Japan started life as a Chinese tailor. Before he died, by raids and intrigues he commanded 3000 sail, and was so powerful that he could not be opposed even by the Emperor of vast Cathay. He became a Christian, and was christened Nicholas. His son, Koxinga, born in Japan, was more powerful than his father, and remains one of the most remarkable characters in Eastern history. In 1662 he drove the Dutch (who had supplanted the Chinese) from Formosa, established a court, promoted industries, enacted wise laws, and ruled a nation of exiles and outlaws. China was helpless against him, and but for his sudden death it seems likely that he would have driven the Spanish from the Philippines. His grandson, a weakling, allowed the "Beautiful Isle" to fall back under Chinese mismanagement, and had these original owners only taken steps to award punishment for massacres and murders of shipwrecked crews, chiefly of foreign nations, Formosa might possibly have remained part of the Celestial Empire until the present day.

In 1874, in consequence of an outrage committed on the crew of a Loochooan vessel, Japan undertook a punitive expedition against Formosan outlaws. This was the thin end of a wedge which, after the war of 1895, was driven home, and Formosa was added to the Japanese Empire. It is, however, yet far from being completely under Japanese jurisdiction. The mountainous and densely wooded centre and eastern parts of the island still safely shelter head-hunting savages, whilst the borderland of these pathless jungles is a home for outlaws, and it is particularly against the latter that the Japanese seem helpless. The difficulty is to find them. At night villages may be looted by a howling mob, but next morning the sun rises upon smiling agriculturists.

After describing the tea industry, we are entertained with a long account relating to camphor. The camphor trees are, unfortunately, within the domains of the Aborigines, with the result that the camphor industry, head-hunting and butchery still go hand in hand. The chief victims appear to be the Chinese, the Japanese being but rarely attacked. Other industries are those of sugar and the mining of coal and gold. When speaking of the sulphur deposits, which are associated with geysers and a variety of spiteful volcanic vents, Mr. Davidson tells us that, in order to prevent certain insurgents obtaining material for the manufacture of gunpowder, an Imperial edict arrived from Pekin ordering officials to destroy all sulphur deposits by fire, and to stop up all offending craterlets which produced this substance. Altogether eighty-eight volcanic orifices were discovered, on which for several years officials paid quarterly calls, and with

perseverance, hope, and clods endeavoured to stop their roarings. This was in 1833.

Long lists and descriptions are given of various plants having an economic value, amongst which we note indigo and other dye plants, fibre plants, paper plants, oil plants, tobacco, coffee, &c., together with some account of forest trees.

The description of the savages is derived from the work of Mr. Y. Ino, who devoted several years to their study. Eight groups are referred to, and for each of these an account is given of their dwellings, dress, ornaments, food, diseases, head-hunting, language, and generally on subjects of anthropological interest. All we have bearing upon zoology is a list of land birds by J. D. de la Touche, and a list of mammalia by the late Mr. Robert Swinoe, the latter, unfortunately, only bringing us up to 1872. Meteorology and seismology are referred to in a short appendix, but about geology Mr. Davidson is practically silent.

With this and a few other exceptions the work is encyclopædic in its character, and it may well be recommended to commercial and scientific men who search for information about the island of Formosa.

THE BASIS OF PLANT-SURGERY.

Pathologische Pflanzenanatomie. By Dr. Ernst Küster. Pp. 300, and index. (Jena: G. Fischer, 1903.) Price 8 marks.

THAT plants have their diseases is a truth that has forced itself more and more on this colonial empire of ours, and that the signs of disease frequently express themselves in abnormal structures and outgrowths is well known to those few experts who have to deal with the galls, cankers, pustules, tumours, and other "malignant" tissue-formations, the very names of which remind us of the ills to which flesh is heir.

Moreover, there is a surgery of plants, as well as of animals, and the true basis of this growing art is in both cases a thorough understanding of the pathological, or diseased, as well as of the normal or healthy anatomy of the patient.

This scientific basis of a refined art is the subject of the work before us.

The author of this treatise had already distinguished himself in Münich by his work on the anatomy of galls, and it is with the greatest satisfaction that we find him inaugurating his career at Halle by a thorough exploration of what is to a large extent a practically new theme, and one, moreover, so worthy of the traditions of his present post, for it is remarkable that, while we have several modern books on physiological anatomy and on the pathology of plants, no competent botanist has given us a detailed and comprehensive treatise on this now important and rapidly extending subject.

Küster's book consists of 300 pp. of excellent and clearly-written matter, illustrated by 121 figures not always worthy of his text, though never obscure or irrelevant.

He divides his subject into six chapters, of which five are devoted to technical and special descriptive anatomy as modified from the normal by pathological changes in the life-work of the tissues and cells, while the sixth is told off to do duty as a general account of the pathological processes themselves, and of what little theory we as yet possess on the subject.

Much as we admire the collection of anatomical facts, and the descriptions of morbid anatomy in special cases, comprised in these first five chapters, it must be evident that the subdivisions are somewhat unfortunate. The author himself apparently sees this, as is evinced by the uncertainty as to which heading certain cases shall be placed under, and we believe that the shortcomings are partly due to a somewhat slavish following of the terminology of the animal pathologists.

These headings are:—I. *Restitution,* under which are placed cases in which changes in growth, induced by sections and wounds, lead to the new formation of the cut-off parts, or to proliferations of various kinds.

II. *Hypoplasie,* or arrested development of organs or parts due to various inhibiting reactions, which bring about diminutions in the number or sizes of cells, or otherwise change the tissues so that they stop short of a stage of development which would normally be regarded as complete.

III. *Metaplasie,* or progressive changes due to overstimulations which result in the cells and tissues undergoing structural changes in excess of the normal, though not suffering the enlargements or increase in numbers dealt with under the next and the fifth heading.

IV. *Hypertrophie,* where the cells attain dimensions more or less inordinate, and due to excessive growth while young and turgid. Most galls—in the widest sense—afford examples of these cases, which are extremely common.

V. *Hyperplasie,* or those abnormalities—usually enlargements and distortions—which owe their origin to inordinate increase in the average numbers of cells.

It is, of course, impossible to discuss examples of these various cases of abnormal anatomy here, and we have already expressed our satisfaction with the general subject-matter. We may note in passing that while Miss Dale's beautiful work on "Intumescences" is properly acknowledged, and one of her excellent illustrations suitably used on p. 86, the best results of her ingenious experiments on the kind of light which induces these abnormalities are not adequately given or apparently apprehended in the summary on p. 87.

To most readers, however, it will be the subject-matter of chapter vi. which will prove most attractive, though there is disappointment in store for anyone who expects anything beyond the most sketchy survey of the factors concerned in ætiology and development and their bearing on pathology. The sections on stimuli and reactions seem to us particularly weak, and the conclusion that any tissue can give rise to any tissue element—"aus jeden Gewebe kann alles werden"—may appear too lightly arrived at unless the reader is acquainted with the somewhat voluminous literature. The same, perhaps, applies to Küster's conclusion that tissue-elements quite foreign to the

species may arise in a pathological structure, though in our opinion he establishes his contention.

The book is undoubtedly a stirring contribution to botanical science, and ought to stimulate research in many directions, and although it escapes the responsibilities of being a great work, it is certainly one that must be on the shelves of every investigator of first rank who has anything to do with the anatomy or pathology of plants. We cordially welcome this interesting book as a pioneer work of what will grow to be an immense subject.

COMETS AND THEIR TAILS.

Comets and their Tails, and the Gegenschein Light. By Frederick G. Shaw. Pp. 70. (London: Baillière, Tindall, and Cox, 1903.)

THE theory of comet's tails has not yet arrived at its ultimate destiny, which we suppose is that of becoming an orthodox branch of applied mathematics; and consequently it still possesses a fascination for the world at large. True, the phenomena have been discussed by Prof. Bredichin, in a succession of papers that now go back nearly thirty years; but the origin of the forces required for Bredichin's theory is very obscure, and the net result is to excite rather than to remove conjecture. During the last few years the general mental ferment over the new views of the constitution of matter has given a fresh stimulus to speculators in this part of astronomy, and a considerable literature has already gathered round the suggestions of J. J. Thomson, Arrhenius and Deslandres.

Mr. Shaw, whose book now lies before us, is not a follower of any of these schools; he holds that the comet's tail is caused by the rays of the sun being altered (by concentration and refraction) by their passage through the cometic atmosphere, and thus rendered more capable of being reflected from the meteoric matter in the neighbourhood. In other words, the tail does not really exist; it is merely a local illumination of the general circumambient dust of space. The idea bears some resemblance to the now frequently accepted explanation of the lighting-up of the Nova Persei nebula.

After stating this theory, and offering a general justification, the author proceeds to examine the records of the great comet of 1858 in the light of it. For this purpose he uses G. P. Bond's monograph to a considerable extent, a mistake which occurs in the first plate of the Harvard astronomer's account being unfortunately twice reproduced; the point chiefly dwelt on is the sympathy between the phenomena of the nucleus and those of the tail.

The work as a whole is brief, its tone is very modest, and it is not claimed that the theory has been worked out in detail. It is therefore scarcely fair to blame the author for the difficulty which one finds in attempting to explain by causes of this kind the singularly complex character of cometary appendages. But any theory of the kind must offer some explanation of their most constant and remarkable features, such as the multiplicity of tails, their curvature, and the "broken" appearances often seen; and it may be doubted whether the author's theory in its present state is capable of meeting these demands. "So-called secondary tails, &c.," he accounts for "by irregular ebullitions of gas from the comet," presumably giving rise to special fields of refracted rays.

But at the root of the whole matter lies the question of whether refraction in the cometic envelope is likely to take place at all on a scale comparable with that required by Mr. Shaw's hypothesis, and at present observation seems to negative this possibility.

The latter part of the book is devoted to the Gegenschein, for which a similar explanation is given—the refraction being in this case produced by the earth's atmosphere, and the phenomenon being due to the reflection of this refracted light from meteoric dust. An interesting criticism of Barnard's views is given.

OUR BOOK SHELF.

Physical Chemistry for Physicians and Biologists. By Ernst Cohen. Authorised Translation from the German by M. H. Fischer. Pp. ix+343. (New York: Henry Holt and Co., 1903.)

PHYSIOLOGISTS and pharmacologists have from the first been ready to adopt and apply the recent theories of physical chemistry. Indeed, the eagerness with which these theories have been received by biologists has frequently led to their misapplication, inasmuch as the conditions existing in the animal organism are so widely different from those for which the theories were developed, that direct adoption of purely physicochemical results is in nine cases out of ten inadmissible. In the book before us we have a series of seventeen lectures delivered by an energetic worker in pure physical chemistry to an audience of physicians. The physicochemical principles bearing on biological problems are expounded, the chief methods of experiment adequately described, and, what is of most importance, a critical account is given of many of their applications. These applications include, for example, disinfection in the light of the theory of electrolytic dissociation, the pharmacology of complex mercury salts and of uric acid solvents from the same point of view, the taste of dilute solutions, osmotic analysis, and the toxicity of electrolytic solutions. The book is admirably adapted to its purpose, and may be heartily recommended.

Trapper "Jim." By Edwyn Sandys. Pp. ix+441; illustrated. (New York and London: Macmillan and Co., Ltd., 1903.) Price 6s. net.

ALTHOUGH, as indicated by its title, this admirable little volume is devoted rather to sport and trapping than to natural history, yet it contains scattered through its pages such excellent descriptions of the wild life of the United States that the naturalist cannot fail to find much valuable information with regard to the habits of many of the mammals and birds mentioned. Specially interesting are the notes on the various species of American hares, and it will come as a revelation to many that the so-called "jack-rabbit" (*Lepus callotis*) is probably the fleetest member of all its tribe. Many references are made to the need for the cultivation of a true sporting instinct among hunters; that is to say, to the enjoyment of the sport itself, as distinct from making a "big bag." The name of Mr. Sandys is too well known as a writer on the sport and popular natural history of North America to stand in need of any commendation on our part, but we may safely say that his popularity will certainly be enhanced by his latest effort. R. L.

Das Gesetz der Translation des Wassers. Von T. Christen, Oberförster. Pp. viii + 179; with one lithographed plate. (Leipzig: Wilhelm Engelmann; London: Williams and Norgate, 1903.)

MUCH has been written about the flow of water in pipes, channels, and rivers, considered from the point of view of the hydraulic engineer, and many attempts have been made to obtain empirical formulæ for purposes of numerical calculation. In this volume the author proposes the formula $v=k\sqrt[3]{(QI)}/\sqrt[4]{B}$, where v is the mean velocity, Q the total flow per second, I the gradient as a sine, and B the half-breadth of the channel. A comparison of the results of the author's formulæ is made, both with the results of experiment and with those of other writers, especially Bazin, and calculations are given of the velocity curves for different sections and under different conditions. Reynolds's critical velocities are also discussed. The book contains a bibliography, tables of coefficients, and a diagram of the author's experiments and of velocity curves.

The new laws are admittedly only empirical, and the author indicates that many points might with advantage be discussed at greater length, but he has certainly succeeded in including a large amount of important and suggestive information in a book of small compass, and his theories will be read and discussed with the greatest interest by hydraulic engineers and experimenters who have worked in the subject.

Colloquies of Common People. By James Anstie, K.C. Pp. 530. (London: Smith, Elder and Co., 1902.)

THE English language contains few good specimens of the philosophical dialogue, perhaps none except the masterpieces of Berkeley. In attempting to revive this most difficult form of composition Mr. Anstie has ventured on a daring task, and I fear cannot be said to have achieved a great success. Like others before him, he forgets that a dialogue is intolerable unless its author is dramatist enough to confer individual character on the interlocutors; nothing is heavier reading than wedges of disquisition by mere puppets. Of the variety of topics handled by Mr. Anstie's puppets it is impossible to give any summary, as they appear to begin their discussion anywhere and to argue anyhow. They seem, however, in the course of his five hundred odd pages to touch on most of the current topics of ethics and psychology. The reader should at least have been assisted to follow their excursions by a table of contents and an index. A. E. T.

A Country Reader. II. By H. B. M. Buchanan, B.A. (Cantab.). Pp. viii+233; with illustrations. (London: Macmillan and Co., Ltd., 1903.) Price 1*s.* 6*d.*

As Mr. Buchanan says, a child is much more likely to learn to read fluently and with intelligence if his reading book is concerned with subjects falling within his everyday experience, and from this point of view the set of readers, of which this is the second, will prove useful and popular in rural primary schools. The various sections of the book deal in simple, interesting language with the characters and uses of the goat, the donkey, the cat, our common reptiles, the fish of our ponds and streams, pastures and grasses. The illustrations are numerous and exceptionally good, though it is a pity the author has omitted to indicate the scale of the drawings; there is some fear, for instance, that quite a wrong idea of the relative sizes of the carp and minnow will be obtained by the pupil from the pictures which face one another on pp. 96 and 97.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Gases Occluded by Radium Bromide.

RUTHERFORD AND SODDY (*Phil. Mag.*, 1902, p. 582; 1903, p. 453 and 579) pointed out that the almost invariable presence of helium in minerals containing uranium indicated that that gas might be one of the ultimate products of the disintegration of the radio-elements. Rutherford, moreover, determined the mass of the projected particle which constitutes the "α-ray" of radium (*Phil. Mag.*, 1903, p. 177) to be approximately twice as great as that of the hydrogen atom, an observation which points in the same direction. These α-particles are readily absorbed by solids, and should accumulate in the solid salts of radium and in the radio-active minerals.

We have been engaged for some months in examining the spectrum of the "radio-active emanation" from radium, and during this work the opportunity presented itself of examining the gases occluded by 20 mgrs. of radium bromide which had been kept for some time in the solid state. These gases, which are continuously generated, have already been partially examined by their discoverer, Giesel, and by Bodländer (*Ber. deutsch. chem. Ges.*, 36. p. 347), and found to consist mainly of hydrogen and some oxygen. We have found that after removing hydrogen and oxygen from the gases evolved from 20 mgrs. of radium bromide, the spectrum showed the presence of carbon dioxide. On freezing out the carbon dioxide, and with it, a large proportion of the radium "emanation," the residue gave unmistakably the D_3 line of helium. This was confirmed by sealing off the tube, and comparing its spectrum with that of a helium tube. The coincidence of the two lines may be taken to be at least within 1/10th of the distance between D_1 and D_2, or say 0.5 of an Ångström unit.

This observation, if confirmed, substantiates the theory already mentioned, and brings ordinary methods to bear on the changes occurring in radio-active bodies.

WILLIAM RAMSAY.
July 10. FREDERICK SODDY.

P.S. (July 13).—We have repeated the experiment with 30 mgrs. of fresh radium bromide, kindly placed at our disposal by Prof. Rutherford, which had probably been kept for several months in the solid state. Entirely new apparatus was constructed for the purpose, and better precautions were taken to exclude from the spectrum tube carbon dioxide and the emanation. The spectrum was practically that of pure helium, with the addition of two new lines. The lines identified are:—

Red	6677	Green-blue ..	4932
Yellow (D_3) ...	5876	Blue	4713
Green	5016	Violet	4472

The additional lines are one in the red and one in the green; these we have been unable to identify.

The Extirpation of Culex at Ismailia.

I BEG to enclose for publication the translation of a report received from the general secretary of the Suez Canal Company regarding the effects of the anti-malaria campaign at Ismailia since the visit of Sir William MacGregor and myself last September. While it is obviously too early to speak definitely regarding the result on the malaria rate, the secretary is able to announce that mosquitoes of the genus Culex "ont été supprimés d'une mannière presque

absolue." Under the term Culex, I think he means to include also gnats of the genus Stegomyia.

I have received confirmatory evidence from a gentleman in Egypt, who says that he was recently able to sleep at Ismailia without mosquito nets.

The campaign against Culex at Ismailia originally promised to be a difficult one, owing to the large number of sewage-cisterns under the houses, and the result shows how easily a simple and obvious idea like that of diminishing mosquitoes by dealing with their breeding places can be acted upon by an intelligent and effective executive which sets to work at once, instead of wasting time on useless discussions—as, for the most part, we have been doing in British possessions during the last four years.

It is to be hoped that, following the work of Gorgas at Havana, and Logan Taylor at Freetown, the result at Ismailia will be accepted as clinching the proof of the fact that Culex, at least, may be materially diminished in tropical towns. RONALD ROSS.

Liverpool, July 11.

TRANSLATION of letter, dated July 2, from M. le Secrétaire général de la Compagnie universelle du Canal maritime de Suez, Paris, to Major Ronald Ross, Liverpool School of Tropical Medicine:—

"Sir,—I have the honour to inform you that, following your mission of last September, numerous works of drainage and filling up of ditches have been effected, and that a permanent department has been created for the purpose of oiling cisterns and pits and suppressing marshes and pools of water amongst the habitations of Ismailia. Moreover, measures of prophylaxis, consisting of the gratuitous distribution of quinine and arsenic, commenced in the month of April, 1902, are continued without interruption.

"Since last December, the number of cases of fever has very sensibly diminished by comparison with previous months and with the corresponding period of last year, and this decrease is maintained until to-day.

"Owing to the time at which the sanitary works were undertaken, the complete disappearance of the Anopheles is not yet realised, but it can be stated that recently captured insects have not been infected—which can perhaps be attributed to the fact that the number of cases of fever have been considerably reduced.

"On the other hand, it is interesting to note that, thanks to methodical *pétrolage*, and to the incessant surveillance of the breeding-places of mosquito larvæ, the mosquitoes called Culex have been suppressed in a manner almost absolute, and that, in the hottest period of the year, it has been possible to abandon the use of mosquito nets.

"Regarding the consequence of these measures, a definite statement cannot be made until after August to November next, the principal malaria season. We have every ground for hoping that the efforts with which you have been so usefully associated will end in the complete extinction of malaria in the town of Ismailia, and we will communicate with you when we receive definite information on this interesting subject."

Another White Spot on Saturn.

ON July 9, at 14h. 4m., I observed another large white spot in the northern hemisphere of Saturn, and on the central meridian of the planet. The spot was quite bright in contrast with the dark belt adjoining it, and a tolerably easy object. I saw the spot again on July 12, when it shone with a bright pearl-like aspect, and was estimated on the central meridian at 12h. 50m. The marking is much distended in longitude, and this makes it rather difficult to note its central passages accurately, but the motion of the object seems decidedly swifter than the rate usually adopted for the rotation period of Saturn.

The following end of a bright extension on the eastern side of the spot was on C.M. at 13h. 35s. on July 12, and a dusky patch between the N equatorial belt and the polar shading followed at 14h. 1m.

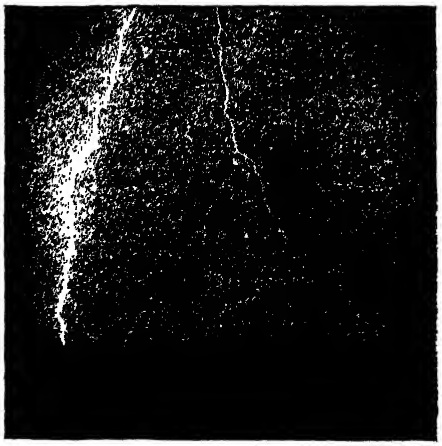
The markings above alluded to are quite different from the bright spot seen by Barnard on June 23, and by myself on July 1. The present disturbance on Saturn seems to have affected a very large area, and I have never observed anything of the same conspicuous character on the planet in past years. W. F. DENNING.

Bishopston, Bristol.

The Thunderstorm of May 31.

MR. C. H. HAWKINS, of Croydon, has sent me a copy of a photograph of a lightning flash taken by him at "Addiscombe," Croydon, on Whitsunday morning, May 31, at 2.30 a.m.

The upper part of the main flash and the side flash both show reduplication, and the photograph exhibits so many



Lightning discharge photographed at Addiscombe, Croydon, on May 31, at 2.30 a.m. Direction N.N.W.

characteristic features that its reproduction may be of service for comparison with other photographs.

I therefore enclose a copy with Mr. Hawkins's permission.

Meteorological Office, S.W., July 7. W. N. SHAW.

THE LODGE-MUIRHEAD SYSTEM OF WIRELESS TELEGRAPHY.

THE system of wireless telegraphy which Sir Oliver Lodge and Dr. A. Muirhead have been developing for some years has, within the past few months, been brought to a degree of perfection which justifies the inventors in the belief that it is now of practical commercial value. Thanks to the courtesy of Messrs. Muirhead and Co., we have had an opportunity of seeing the system at work at a small experimental installation which has been put up in a field adjoining Messrs. Muirhead's works at Elmers End, Kent. At this station signals were being transmitted to and received from a similar installation at Downe. The distance between the two stations is only six or seven miles, but the chalky nature of the Kentish soil and the fact that the station at Elmers End lies in a hollow make this distance equivalent to eight or nine times as much over water. Experiments which have been made under the conditions which would obtain in the practical application of the system for maritime work and also over the Admiralty sixty-mile range have shown that, with the same power and the same adjustments as are required between Elmers End and Downe, thoroughly satisfactory communication can be maintained across sixty miles of ocean. Considerations of distance are, however, of secondary importance in estimating the merits of wireless telegraphy systems, for the recent work of Mr. Marconi and others has made it clear enough that, given sufficient power, almost any range can be attained. Trustworthiness, clearness, the design of circuits and apparatus, and the possibility of successful syntonisation are factors of greater importance. Looked at from this point of view, the Lodge-Muirhead system presents several novel and interesting features which show that, though it may be one of the latest to come into the field of practical wireless telegraphy, it is likely to prove one

of the most efficient. Most noteworthy feature of all is the remarkably delicate coherer which has been finally evolved from numerous experiments, a coherer which not only promises to be accurate and trustworthy in practical work, but also possesses several advantages from an experimental point of view, a characteristic of no small importance in a piece of apparatus which has to be employed in an art in which there is so much to be learnt.

In general outline the Lodge-Muirhead system does not differ materially from other wireless telegraph systems, a fact which is not remarkable when it is recalled how much other systems owe to the pioneering work which Sir Oliver Lodge has carried on ever since the earliest days of Hertzian waves. In fact, if we retrace the development of Hertzian telegraphy from Maxwell's theory of light, the name of Sir Oliver Lodge is singularly prominent, and must be associated with all the more important advances. The connection begins in 1888, when he read a paper on the velocity of electromagnetic waves along wires at the meeting of the British Association, at which Prof. Fitzgerald directed attention to the work that Hertz had accomplished; a little later he discovered, in its simplest form, coherer action, and it is interesting to note that after long trial of the filings coherers derived from the discoveries of Branly, there seems to be a tendency on all sides to return to simpler designs much more closely resembling Lodge's original single contact coherer. To Lodge also belongs the credit of having been the first to insist upon the importance of tuning, and of having pointed out how this might be possibly attained by the proper use of self-induction and capacity. Moreover, it was, we believe, he who suggested using a transformer in the aërial circuit at both transmitting and sending stations instead of connecting the spark gap or coherer direct to the aërial; this device is now in general use for tuned systems. It will readily be realised, therefore, that a system which has been designed by Sir Oliver Lodge is likely to be one of the most promising of wireless telegraph systems, and that this is all the more likely to be the case in the present instance, as Sir Oliver has had the cooperation of Dr. Muirhead.

We do not propose to give a general description of the system, for, as we have said, other systems are similar in general outline, and with these most people are by now familiar. In the installation working between Elmers End and Downe there is no earth connection. The precise utility of an earth connection has been often in dispute, most people maintaining that it merely serves to introduce the earth as the second plate in a large condenser, the first plate being represented by the aërial wire and any capacity connected to it. In the system under consideration, a second capacity is provided which lies upon but is insulated from the earth; in the Elmers End station the capacity was beneath the floor of the instrument shed, and was connected to one terminal of the spark gap (or transformer), the other terminal being connected to the aërial, which has an open wire cage serving as a suitable capacity at its upper end. We need not enter here into the various ways in which the circuits can be connected up; the relative positions of coherer, spark gap, capacity and self-induction, the employment or not of the transformer, &c., offer a number of solutions to the problem of designing a complete station each of which has its special merits for particular purposes. In principle, all result in the same thing—a very large Hertz radiator transmitting into space a succession of untuned or carefully tuned electromagnetic waves. The two questions of primal importance are how to produce those waves, and how to detect them at the receiving end.

FIG. 1.—Complete Lodge-Muirhead Apparatus.
From left to right as follows:—Battery, receiver, spark gap, induction coil, signalling key, buzzer (at the back), automatic transmitter, and perforator.

The production of the Hertzian waves presents several difficulties. Even for moderate ranges of transmission fairly powerful sparks have to be used; these are obtained from a special induction coil and spark gap (Fig. 1). Here again one notices in the simple spark gap between two rods a return to less complicated apparatus; in the early days of wireless telegraphy a spark gap between polished balls in oil or vaseline used to be regarded almost as essential. In using this apparatus for syntonic work a very great deal depends upon the spark. It is necessary, in the first place, to obtain a regular succession of sparks for every depression of the signalling key. The ordinary forms of make-and-break used with induction coils have not been found satisfactory, and a special form of interrupter or "buzzer," as it is called, has been designed. This is seen at the back on the right of Fig. 1. It consists of an ordinary mercury break operated by two cross-connected telegraphic sounders. The first of these sounders works in the same manner as an ordinary electric bell, the arm vibrating to and fro when the signalling key is de-

pressed and the circuit closed; the vibrating arm opens and closes the circuit of the second sounder, to which is attached the dipping rod of the mercury break. It is said that this arrangement gives a more regular succession of sparks than is obtained with one sounder only. An automatic transmitting apparatus has also been worked out by Messrs. Lodge and Muirhead. This is shown at the right of Fig. 1, in front of the buzzer, and consists of two pieces of apparatus, a perforator and a transmitter, which are used in conjunction with the buzzer, &c., in place of the ordinary signalling key.

A regular succession of sparks having been thus obtained, still only part, and that the simpler part, of the difficulty has been overcome, for it is not the period of the sparks but the period of the oscillations in the spark which has to be syntonised. When one considers how short is the train of waves from each individual spark and how long comparatively the interval between two successive sparks, it is easy to see the importance of getting the best results possible

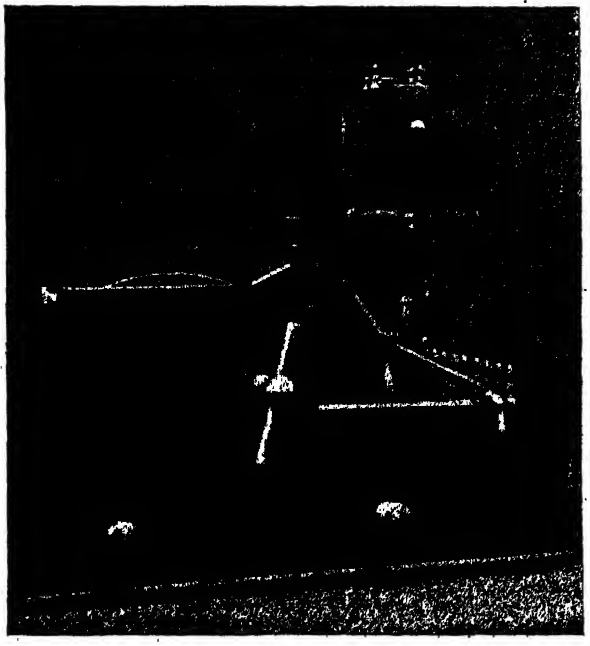


FIG. 2.—Receiving Apparatus.

from each spark. Herein, indeed, seems to lie one of the chief unsolved problems of wireless telegraphy—the problem of obtaining a really continuous series of undamped oscillations. It seems doubtful whether, even with the best possible design and arrangement of apparatus, a satisfactory solution will ever be found by means of disruptive sparks. Perhaps we must look to some quite different method of setting up the oscillations. The method that gives most promise of ultimate success is some application of the principle of Mr. Duddell's musical arc, as suggested by Mr. Duddell at the Royal Institution last year (see also the *Electrician*, May 1, vol. li. p. 84). It certainly seems that from this discovery may be developed a means of producing a continuous series of undamped oscillations of high frequency, and if this should prove to be possible a change amounting almost to a revolution would be effected in the practice of syntonic wireless telegraphy.

We may pass now to a consideration of the receiving instruments which are shown in Fig. 1, and in more detail in Figs. 2 and 3. Fig. 2 represents the complete receiving instrument. The instrument looks at first sight much like a Morse recorder; the coherer is mounted behind the box which contains the clockwork for feeding forward the tape and rotating the coherer wheel. Its construction can be seen from Fig. 3, which shows a coherer by itself. It consists of a small steel disc with a fine razor edge which dips into a little pool of mercury in an ebonite cup. The mercury is covered by a thin film of oil, and the disc is adjusted so that under normal conditions the oil serves just to insulate it from the mercury. When oscillations are set up in the coherer circuit, this thin layer of insulation is broken down, and connection established between the disc and the mercury. The disc is slowly rotated by means of the notched wheel seen clearly in the illustration, which gears with a similar wheel at the back of the clockwork box. Connection is thus no sooner established between the disc and mercury than it is broken again by a fresh oily portion of the edge coming round; there is consequently only connection during the time the oscillations are actually arriving and the

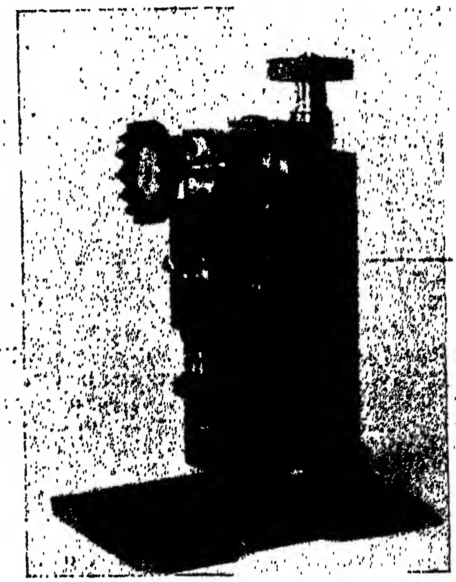

FIG. 3.—The Coherer.

coherer is self-decohering and requires no tapping back. In some respects the device recalls a suggestion made by Rupp five or six years ago, who proposed mounting a filings coherer so that it was rotated slowly by the Morse tape. The Lodge coherer is, however, a far more mechanical contrivance than a filings tube however the latter may be decohered. In order to keep the edge of the disc clean a pad of felt is pressed lightly against it; this can just be seen on the left near the top of the disc; contact is made by a spring pressing against the shaft on which the disc is mounted. The coherer will only work with a very small potential difference—a fraction of a volt—between mercury and disc; it is therefore connected in series with a potentiometer, which reduces the voltage from the cell.

Another feature of the receiving circuit is the absence of any relay; the coherer and potentiometer are directly in series with the recording instrument, which takes the form of a simple syphon recorder. This is seen on the right of the clockwork in Fig. 2; the pen consists of a fine glass syphon tube suspended from the galvanometer coil, one end dipping in a cup of ink

and the other resting on the tape. When no signals are being received the pen draws a fine line on the paper, but when a signal arrives it is deflected. The result can be seen from the specimen of tape in Fig 4. There is an arrangement by which the amplitude of the deflection can be controlled by making the syphon come up against a stop. It is obvious that the tops of the humps in the line representing dots and dashes are not needed for reading the message, since it is easy to see from the length of the break in the base line whether the signal is a dot or a dash. The tops of these humps have, however, a special interest. It will be noticed, on examining them closely, that they are not smooth, but are slightly irregular. These irregularities represent the sparks, and it is possible therefore to see from the form of the humps whether the sparking at the transmitting end is good or bad. A particularly bad spark is seen at the beginning of the third signal (the second dot) in the letter *l*, and a careful examination, of the dashes more especially, shows quite clearly the nature of the sparking at the transmitting station seven miles off. This not only points to the great sensitiveness of the coherer, but shows that it should prove particularly useful in research, since by its use one can obviously much better investigate the conditions necessary for good signalling. In spite of this delicacy, it is remarkable how easy the coherer is to adjust. A milled head screw allows the mercury to be raised or lowered at will, and it is quite easy to get proper adjustment in a few seconds, even though one starts with the disc either in permanent contact or right out of contact with the mercury; in fact, the whole coherer can be dismantled and set up again in a few minutes. This coherer seems to us one of the most promising features of the system; it is a device at once quite simple and thoroughly mechanical, easy to reproduce, and easy to adjust, and, judging by the results which have been obtained, is both sensitive and trustworthy in practical work. So far as one can judge without lengthy experiment, it is more promising than any other form of receiving apparatus yet devised.

We may add that the system has been adopted by the Eastern Extension Telegraph Company on its two new cable ships, and is reported to be giving every satisfaction. In conclusion, we should like to express thanks to Messrs. Muirhead and Co. for showing us the system at work, and for lending the photographs from which the illustrations to this article have been made.

MAURICE SOLOMON.

THE ALLIED COLONIAL UNIVERSITIES CONFERENCE.

A STRONG committee—Sir Gilbert Parker being the moving spirit—addressed the following circular letter to the universities of the United Kingdom on May 30:—

In order to facilitate the proceedings at the Allied Colonial Universities Conference, to be held at Burlington House on July 9, I shall be very much obliged if you can assist me with information upon the following points:—

(*a*) Whether, and if so in what way, the conditions under which degrees are given by the University of —— are modified in the case of persons who have studied in or taken the degrees of colonial universities.

(*b*) Does the University of —— afford any special facilities for post-graduate study (in particular with regard to applied science) to the graduates of colonial universities? Does the university reward special post-graduate students by bestowing upon them degrees, and on what conditions as to residence or tests of fitness are such degrees bestowed?

(*c*) Does the University of —— possess any special endowments for the encouragement of colonial students; or are colonial students habitually aided by any endowments not under the control of the university?

(*d*) What is the average number of colonial students studying in the University of ——?

The colonial universities (with the exception of the universities of India) had meanwhile been asked to appoint delegates to represent them at the conference, with the result that, when the conference opened, almost every university within the Empire was directly represented.

The actual session occupied one day only, but a good deal of hospitality was exhibited during the week, and whatever view may be held as to the value of the business actually transacted, there can be no question as to the quality of the entertainment provided. The informal meetings between the delegates, both before and after the session day, constituted probably the most important part of the conference; the opportunity for interchange of ideas was absolutely unparalleled in the history of British education, for not only were the delegates drawn from practically every university within the Empire, but they were, on the whole, exceptionally well qualified for their duties. It is not possible to set down in writing a precise estimate of the advantage to be drawn from informal conversations between those who are interested in the same things but have few opportunities of discussing them; the British Association, however, affords a proof, repeated annually, that there is a very important advantage to be gained in this way. Those engaged in carrying on university work in new countries and in communities where the importance of that work is not always properly understood, are apt to wonder now and again whether they are really on the right track, whether their work is, after all, as important as they have been in the habit of thinking it is, and whether their methods are sound and progressive. To such men the stimulus of a conference such as the one just over is invaluable, and the chance of learning at first hand what others are doing is also invaluable.

To come to the conference itself. The chairman, Mr. Bryce, called the meeting to order with commendable punctuality, and explained in a scholarly way—though in the most general terms—how universities might cooperate to their mutual advantage. The Vice-Chancellor of Cambridge then proposed the first resolution:—

"That in the opinion of this conference it is desirable that such relations should be established between the principal teaching universities of the Empire as will secure that special or local advantages for study, and in particular for post-graduate study and research, be made as accessible as possible to students from all parts of the King's dominions."

This was supported with businesslike brevity by various delegates both from the United Kingdom and from Greater Britain, and was finally passed without dissent. From the discussion the following principles finally emerged:—

(1) There must be no thought of attempting uniformity of regulation—each university must decide for itself how it should treat post-graduate students from other universities.

(2) The question at issue was, for practical purposes, to be limited in the first instance to the consideration of post-graduate facilities. In this connection it was shown by Sir Henry Roscoe that the scholarship system of the Commissioners of the 1851 Exhibition had proved itself to be a great success, and Prof. Ewing showed that the Cambridge "research tripos" had also succeeded beyond all expectation.

Cambridge appears to be the only university which, so far, has provided satisfactory machinery for post-graduate students of other universities, and one of the objects of the conference was to induce other universities to show themselves as liberal as Cambridge in this respect.

(3) It appeared that more scholarships on the lines of the Commissioners of the 1851 Exhibition were needed, and could be worthily allotted.

(4) The magnificent hospitality of the University of France and of the universities of Germany at present attract a large number of British students. It was felt that, though this might be regretted on sentimental grounds, the only legitimate manner of dealing with it was to provide within the King's dominions at least as great freedom and facility for study as could be obtained abroad.

It was abundantly clear that the delegates, as a whole, were extremely well informed on educational subjects. For instance, it was practically taken for granted by all the speakers that there can be no serious education which does not embrace a certain amount of research work; the only speaker who did not appear to endorse this view being Prof. Mahaffy, of Dublin, who was witty on the subject in the well-known mid-Victorian manner. Since Germany has given to our disadvantage a definite experimental proof of the success of research as an instrument of education, the delegates probably felt that the matter had gone beyond the range of academic discussion.

It was also interesting to note that the principle of "examination by the teacher" appeared to be fully admitted on all hands.

The afternoon session was devoted to a quite similar discussion on a motion for the appointment of a standing committee. The committee so proposed did not explain in any way what steps it intended to take, nor did any speaker ask it to do so, or make any very distinct suggestion as to its duties, so that future developments must depend entirely on personal initiative within the committee. It would have been better, probably, had the committee been less reticent.

On the whole the conference must be regarded as having met with a quite unanticipated measure of success. There was an enthusiasm and go about it throughout which was most stimulating, and of the best possible augury for the future of English-speaking university education. If secondary education could be brought up to a corresponding standard, we should be much better off than we are.

The proceedings culminated in a huge dinner of about 500 people at the Hotel Cecil on the evening of July 10, with Mr. Balfour in the chair, and at his best in proposing the toast of the evening afterwards.

The conference was excellently managed throughout, and it is fair to say that a good deal of the success attained must be attributed to the exertions of the honorary secretary, Mr. Kinloch Cooke. A conference for which no precedent exists requires, in the words of Lord Palmerston, "a lot of bottle-holding," and Mr. Kinloch Cooke appeared to be equal to all the demands made upon him.

R. T.

MR. BALFOUR ON ACADEMIC AND SCIENTIFIC EDUCATION.

We reprint from the *Times* of July 11 the report of the speech made by Mr. Balfour in proposing the toast of the evening, "The Universities of the King's Over-Sea Dominions" at the Allied Colonial Universities' dinner on Friday last:—

We are here, if I may venture to say so, a remarkable gathering in the individual capacity of the members who compose it. But I think we are still more remarkable taken in connection with the central idea which has brought us together. It is not merely, or simply, or chiefly that there are in this room the representatives of scholarship and science, of all the great spheres of activity in which modern thought is indulging itself. It is that we are here representing what will turn out to be, I believe, a great alliance of the greatest educational instruments in the Empire—an alliance of all the universities that, in an increasing measure, are feeling their responsibilities, not merely for training the youth which is destined to carry on all the traditions of the British Empire, but also to further those great interests of knowledge, scientific research, and culture without which no Empire, however materially magnificent, can really say that it is doing its share in the progress of the world. I think that we who in this room belong to the old country, and who were educated in the older universities of England, of Scotland, or of Ireland, have great reason to be proud of those who may be described as our educational children—I mean the universities of the other portions of the Empire.

We boast of community of blood, of language, of law, of literature; but surely we may also boast, and with not less reason, that the ideals of education which are working a great work in the old country are now doing their work among its younger children, and are carrying on in all the self-governing nations of the Empire work like that which they perform in the parent country. Now, my lords and gentlemen, I have mentioned two subjects already in the few sentences I have uttered which, each separately, has been exercising the minds, at all events, of people on this side of the Atlantic—the ideals of education and the ideals of Empire. We have been quarrelling—it would, perhaps, not be too much to say we are still quarrelling—over both. I ask you to consider them in conjunction, but I hope that the two elements brought into this chemical composition will prove less explosive than they do in their separate and individual character. At all events, I am certain that nothing I shall say will hurt the sentiments even of the most ardent opponents of the Education Act passed through Parliament last year, or will in the smallest degree anticipate that interesting discussion upon tariff reform with which it is promised us that the autumn is to be occupied. I mean to talk of education, and I mean to talk of Empire; but I hope and believe I shall tread upon nobody's toes, and that is partly because I think I am justified in treating very lightly on an occasion like this that part of the great educational problem which touches upon secondary education. I confess that, as far as I am concerned, I have never been able to make a theory satisfactory to myself as to what is or is not the best kind of education to be given in those great public schools which are the glory of our country, and which, in their collective effect upon British character, I think cannot be overrated, but which are subjected, and perhaps rightly subjected, to a great deal of criticism as to that portion of their efforts which is engaged on the scholastic and technical side of education.

I cannot profess myself to be satisfied with the old classical ideal of secondary education; and yet I am not satisfied—perhaps I ought to put it more strongly and say I am still less satisfied—with any substitute I have seen for it. I have heard the old system defended on the ground that the great classical languages contain masterpieces of human imagination which have never been surpassed; and, of course, that is true. But I do not think we can defend classical education in the great public and secondary schools on that ground alone. You have only got, after all, to make a simple statistical calculation, which perhaps we cannot put down in figures, but which every man with

the smallest experience, perhaps with the smallest memory of what he was and what his school fellows were at the age of seventeen or eighteen, can make, to know that the master of the dead languages of a kind which enables them to enjoy those great works with their foot on the hearth, which is the only way to enjoy any work of literature, the number of boys who leave the great public and secondary schools with that amount of knowledge is a very, very small percentage. You cannot keep up a system of education for a very, very small percentage; and, if that is the only defence of classical education, I think it will have to be abandoned except for the few who are qualified to derive all the immense advantages which to the few they are capable of imparting. But when I turn to the other side and ask what the substitute is, then I confess I am even less happy than when I consider the classical ideal; for I am quite sure—no, I am not quite sure, but I think—you will never find science a good medium for conveying education to classes of forty or fifty boys who do not care a farthing about the world they live in except in so far as it concerns the cricket field, or the football field, or the river—you will never make science a good medium of education for those boys; for only a few are capable at that age, and perhaps at any age, of learning all the lessons which science is capable of teaching. I go further. I never have been able to see, so far as I am concerned, how you are going to get that supply of science teachers for secondary schools who have both the time to keep themselves abreast of the ever-changing aspects of modern science and to do all the important work which the English schoolmaster has to do, which is that not simply of teaching classes, but of influencing a house and impressing moral and intellectual characteristics on those committed to his charge.

I do not know whether it was Lord Kelvin's presence which inspired me to say something which I was afraid he would not like. I did not mean to deal with this topic at any length. I only meant to say that while, as far as I am concerned, I think we have not yet arrived at the ideal system or the ideal character of our secondary and public school education, I do think that, so far as this assembly is concerned and the universities are concerned, we are on much more solid ground when we come to the education with which they have got to deal; and especially and chiefly do I say that we are on absolutely secure ground when we are dealing with that post-graduate education which, I hope, will be the great practical result, or one of the great practical results, of the meeting which I am addressing to-night. We know exactly what we want when dealing with post-graduate education, and it is our business to see that the students who desire it have it, and that the opportunity of those who do desire it is augmented so far as our influence will go. I daresay that many of us have looked back with a certain regret, and a certain feeling of shame, to the medieval passion for learning without fee and without reward—with no desire to make the universities stepping-stones to good places or to successful mercantile or industrial undertakings—but with an ideal which made thousands of students from every country in Europe undergo hardships which would be regarded in these softer days as absolutely intolerable, for the sole purpose of seeking, and it might be finding, the great secret of knowledge. We despise, and we perhaps rightly despise, their methods. We know that they were not in touch with the actual realities of the world in which they lived. Yet, after all, we have something to learn from them; and if we in these days could imitate their disinterested passion for knowing and for extending the bounds of knowledge, surely we, with our better methods, and our clearer appreciation of what we can know and what we cannot know, might accomplish things as yet undreamed of. Now, what did they do? They moved from university to university, from Oxford to Paris, from Paris to Padua, from country to country, in order that they might sit at the feet of some great master of learning, some great teacher who might lead their thoughts into undreamed of paths. I hope that in the universities of the future every great teacher will attract to himself from other universities students who may catch his spirit—young men, who may be guided by him in the paths of scientific fame; men who may come to him from north or from south; and who, whether they come from the narrow bounds of this island or from the furthest verge of the Empire, may feel that they have always open to them the best that the Empire can afford, and that within the Empire they can find some man of original genius and great teaching gifts who may spread the light of knowledge and further the cause of research.

I have said that they were to find this—I have suggested, at all events, that they should find this—within the limits of the Empire. I hope that in putting it that way I have not spoken any treason against the universality of learning or the cosmopolitan character of science. I quite agree that the discoveries made in one university or by one investigator are at once the common property of the world; and we all rejoice that it is so. No jealous tariffs stand between the free communication of ideas. And surely we may be happy that that is the fact. And yet, though knowledge is cosmopolitan, though science knows no country and is moved by no passion—not even the noblest passion of patriotism—still I do think that in the methods and machinery of imparting knowledge, as there always has been in modern times, so there may still continue to be, some national differentiation in the character of our universities, something in our great centres of knowledge which reflects the national character and suits the individual feeling, and that an English-speaking student and a citizen of the Empire, from whatever part of the world he may hail, ought to find something equally suited to him as a student, and more congenial to him as a man, in some university within the ample bounds of the Empire. If that be our ideal, we have to ask ourselves whether we have accomplished it, or whether we are in process of accomplishing it. I am afraid it is too clear that we have not accomplished it. But that we are in process of accomplishing it, and that we can accomplish it—of that I do not entertain the smallest doubt. The movement which has begun with the inter-university meeting, of which this is the culmination, that movement is not destined to finish with this evening's proceedings. It is but the beginning and the seed of far greater things. And I feel confident that, if the representative men whom I see here gathered together from all parts of the world should by good fortune meet a few years hence in this metropolis of the Empire, they will be able to say, and to say with confidence, that the work begun to-night has not been unfruitful; that the machinery for interchanging ideas between our great academic centres has worked admirable good, not merely for the individual student, and not merely for the cause of knowledge, but for the cause of Empire itself. And while learning ought never to be perverted to the cause of faction, or to the cause of separation between the different sections of mankind, yet nevertheless it will be true that this intercommunication of the highest thoughts between the leaders of academic training in every portion of the Empire to which we belong will have furthered not merely sound learning, but sound patriotism. It is in that faith that I have been proud to share, however humbly, the work on which you are engaged. It is this, I think, that will make memorable in academic history the undertaking which my friend, Sir Gilbert Parker, more, perhaps, than any man in this room, has set himself to accomplish; and it is in the cause of education, of learning, of research, of science, and of Empire that I now ask you to fill your glasses and drink to the toast of the universities of the King's over-sea dominions.

NOTES.

It is proposed to change the name of the Jenner Institute of Preventive Medicine to the Lister Institute of Preventive Medicine. A memorandum which has been sent by the governing body to the members of the institute states, as one reason for the change of name that there is in London a commercial firm trading under the name of "The Jenner Institute for Calf Lymph," with a prior legal claim to the name of Jenner Institute. So great has the inconvenience become on account of the confusion between the two institutes, that the governing body has determined to seek the sanction of their members and of the Board of Trade to change the name of the institute to the Lister

Institute of Preventive Medicine, though it is only fair to Lord Lister to say that this name was chosen by his colleagues against his own strong personal wish.

AT a meeting of the Wilts County Council last week, it was decided not to take over the powers and duties of the Amesbury Rural District Council in regard to the alleged rights of way to Stonehenge. Steps are being taken to ensure that the question of right of way shall be brought before a legal tribunal for decision, as the negotiations between the Government and the landowner for the purchase of Stonehenge have come to an end.

THE *Times* correspondent at Cape Town reports that on July 9 a slight earthquake was felt there at 11.37 a.m., followed by a second shock at 12.6 a.m., the latter being the heaviest known at Cape Town for twenty years. No damage was caused.

IT is proposed to hold an International Exhibition at Manchester in 1905. At a meeting recently held in that city, a committee was appointed to take such steps as they consider necessary to ascertain the views of those likely to be interested in such a project.

IN reply to a question asked in the House of Commons on July 8, Mr. Balfour stated that the King had expressed the wish that the Celtic gold ornaments declared by the judgment in the Court of Chancery to be treasure trove, and therefore the property of the Crown, should be presented as a free gift to the treasurer of the Irish Academy. The ornaments will therefore be taken from the British Museum and sent to Ireland.

THE whaler *Terra Nova* has been bought by the Admiralty to be sent to the relief of the *Discovery* in the Antarctic. The *Terra Nova* left St. John's for the Tay on July 9, and is to be fitted out, by instructions of the Admiralty, by the Dundee Shipbuilders' Company, who constructed the *Discovery*.

A PARIS correspondent writes:—Last week a visit was paid to the Moisson Aërodrome by the scientific committee of the Aëro Club, when the Lebaudy balloon made a successful performance, controlled by M. Juchmès and two assistants. During about twenty minutes the balloon travelled at an altitude of about 300 metres, and travelled in different directions for about a kilometre, in spite of a wind blowing at a measured rate of 6 to 7 metres in a second. The influence of the motion of the air was perceptible only by a great diminution of this velocity and large vibrations testifying to the effort exerted.

AMONG the subjects of resolutions adopted in general conference of the International Fire Prevention Congress, held in London last week, the following are of interest:—that in all reports dealing with questions of fire-resistance and tests, the metric system of measurement, weight, and temperature shall be adopted, as well as any local system; that there should be established testing stations for fire-resisting materials, and a universally recognised method of testing adopted; that courses of study should be provided in universities, technical colleges and schools, for the instruction of engineering and architectural students in the fire-resistance of building materials and the methods of construction as based on investigation; that having regard to the neglect of precautions against damage caused by lightning, the subject should have the serious consideration of the Government and local authorities, the technical professions, and the fire service.

MR. H. C. RICHMOND, of Southport, appreciating the highly interesting work of Jeremiah Horrox, is endeavouring to have erected to his memory some suitable memorial in Southport. Doubtless Mr. Richmond feels that the forthcoming meeting of the British Association in that town will awaken some scientific interest, and make easier the task to which he has applied himself. We can wish him all success in his praiseworthy effort to keep alive the memory of one whose genius has been the admiration of successive generations, and whose early death lent a pathetic interest to his work. Already a suitable tablet to the memory of Horrox exists in the Church of S. Michael in Liverpool, a window and memorial chapel commemorate his scientific zeal in the church at Hoole, and on the walls of Westminster Abbey there is other acknowledgment. Is another tablet precisely the form which the memorial should take? It would be just as fitting, and productive of more lasting benefit to the community, to found a Horrox scholarship for astronomy in the new University of Liverpool.

DR. E. C. HOVEY gives reasons in *Science* why the now celebrated volcano on the island of Martinique should be called by the French name Mont Pelé, and not the Anglicised Mount Pelee, in which there is little suggestion of the true pronunciation of the name.

MR. WALTER ROSENHAIN has sent a reprint of a paper read before the Optical Society of London on June 15, on some properties of glass. It deals with the crystallisation of glass due to heating, the effect of light on the colour of glass, the chemical instability of many of the most desirable optical glasses, and the thermal properties of glass, with especial reference to production of internal strains.

M. F. WORMS DE ROMILLY, whose funeral took place on May 3, has bequeathed to the French Physical Society a sum of 150,000 francs, together with his library and the whole of his apparatus. His telescope, the silvered glass mirror of which was made by Léon Foucault, is either to remain the property of the society or to be given to the National Observatory.

THE electrophorus is such a convenient apparatus for producing electricity for class experiments that the unsatisfactory explanations of its action given in many textbooks are to be regretted. Dr. Otto Geschöser, in the *Beitrage* of the Oels Gymnasium, describes simple experiments tending to show that the action of the electrophorus is to be attributed to "electromotive force of contact" between the resin disc and the metal plate, and that, so far from these acting as the plates of a condenser, the efficiency of the apparatus depends on the perfection of the contact between them. A modified form of electrophorus, in which the contact is made between silvered glass as a dielectric and copper as a conductor, is described.

THE *Bulletin* of the French Physical Society announces the opening of the new Laboratoire d'Essais du Conservatoire des Arts et Métiers. This laboratory has been founded with the assistance of considerable endowments from the Chamber of Commerce, for the purpose of undertaking measurements and determinations for commercial purposes. It consists of five sections, namely, physics, metals, building materials, machines, and vegetable products. M. Perot is director of the laboratory, and M. Raveau head of the physical department. Among other objects of the laboratory may be mentioned the testing of thermometers, and the standardisation of weights and measures where great precision is not required.

IN the *Proceedings* of the Royal Philosophical Society of Glasgow, Mr. R. F. Muirhead discusses a generalisation of Lord Kelvin's statement of the formula for direct refrac-

tion through a thin lens depending on the introduction of the term "divergence." Mr. Muirhead defines the *divergence* of a pencil of rays with regard to a refracting surface as the reciprocal of the effective distance (*i.e.* actual distance ÷ refractive index) of the surface from the apex of the pencil, and the divergivity of the surface as the divergence it produces on a pencil of rays originally parallel. Lord Kelvin's rule that "divergence after refraction equals divergence before refraction plus divergivity" then applies to refractions at single surfaces, and not merely to thin lenses in air.

Several articles on the subject of aërial navigation have lately reached us. Early in the year M. W. de Fonvielle discussed the general problem in the *Revue des deux Mondes*, with especial reference to the Bradsky disaster of October, 1902, and urged the desirability of not abandoning ordinary balloon experiments in favour of attempts with motor-driven balloons. In *Cosmos* for May 23, Lieut.-Colonel G. Espitalier gave an account of the new German balloon station at Renickendorf West, the installation of which includes a hangar 50 metres long, 25 metres wide, and 20·5 metres high. Finally, we have before us a paper by Mr. W. Rickmer Rickmers, entitled "Die Beherrschung der Luft" (Vienna), in which the author condemns as contrary to natural laws the attempts made to navigate the air by mechanically propelled balloons.

Prof. J. Hann presented to the Vienna Academy of Sciences on April 2 a treatise on the air-currents at the summit of the Säntis (2504 metres) and their yearly period. The investigation is based upon the anemometrical observations for fifteen years, and the author has calculated the values of the four wind components for each month, and separately for three five-yearly periods. It was satisfactory to find a considerable agreement of the yearly period of the components in each of the three lustra. The northerly component attains its greatest value in January and February, and its smallest value in July and August. The easterly component has nearly the same yearly period as the northerly, but the maximum in winter is more pronounced, and the minimum is from June to September. The contrast between the winter and summer half-year is very marked. The southerly component has a still more marked yearly range, with a maximum in October and November, and a minimum in June. The yearly period of the westerly component is less regular, but there is a decided maximum in July and August, and a similar minimum in April and especially in May. Among other interesting problems the author also endeavours to trace the relations between this yearly variation of the wind components and the distribution of air-pressure at sea-level. These are, on the whole, well marked, so that the distribution of pressure at a height of a mile and a half cannot differ much from that at the sea-level. The S.-N. component reaches its smallest value in May and its greatest in October; the W.-E. component has also its minimum in May, but its maximum in July and August. The resultant is W. 29° S., and varies but little during the year.

Dr. J. W. Kime, in an article contributed to the *Scientific American* of June 20, gives details of some experiments that show that sunlight will penetrate in a comparatively short time through a considerable thickness of flesh. He bound together a small negative and a gelatino-bromide plate of the ordinary kind (that is, not specially sensitised for colour) and put the combination between the teeth and the cheek of the subject, taking suitable precautions that no light should enter at the mouth. The cheek was then exposed to direct sunshine in February for forty seconds, and in every case it proved that the image was developable. Reproductions of the results of five experiments are shown, each with a different person. One man had a thick, short black beard, and this lessened the exposure effect somewhat. Another was a negro, with a thick, dark cheek; here the diminution in the light transmitted was still more marked. No steps were taken to interfere with the circulation of the blood, and Dr. Kime considers that his experiments show that it is not necessary, as has been stated, to compress the parts to free them from blood as far as possible when light is used as a surgical agent. Dr. Kime also states that his experiments show why red light is valuable in the treatment of small-pox. "They prove that no chemical light of any consequence reaches the patient" when red curtains are fixed over the windows, &c., and so irritation is prevented and subsequent disfigurement lessened. But as the photographic plates used were not sensitive to red light, the soundness of this deduction from the experimental results may be doubted.

It is stated that the radium rays have been successfully applied in the treatment of a case of cancer by Prof. Gussenbauer, of Vienna. The tumour completely disappeared as a result of the application, radium bromide being made use of as a source of the rays. The early publication of these details in the public Press before there has been time to test the method effectually is much to be deprecated.

Prof. Finsen, of Copenhagen, in a note upon the light treatment of lupus (*Acad. des Sciences*, Paris, June 22), points out that it is necessary to employ light of the greatest intensity in order to obtain penetration of the tissues, and states that his results have been much better since employing arc lamps, using a current of 60–80 amperes, than previously with 40 ampere lamps, the former penetrating in 20–25 seconds to a depth which formerly occupied 4–5 minutes.

Drs. Dutton and Todd, of the Liverpool Trypanosoma Expedition to Gambia, have just returned to England. They state that the disease occurs frequently both in natives and Europeans, and that it is distributed from the sea to the Upper Gambia. Besides the human disease, there is also an affection of the horse in the same region, caused by a trypanosoma, and resembling somewhat the "tse-tse" fly disease, but being more chronic. This is in all probability a disease distinct from the "tse-tse" fly disease. A mass of material has been brought home which will necessitate some time to work through.

Mr. B. Timothy sends us from Waterford an abnormal corolla formed by the union of several flowers, found growing on the apex of the stem of a foxglove, and surrounding the stem entirely. A botanist to whom we submitted the specimen remarks in reply that this abnormal development of a foxglove is "a case of *peloria*, that is, a change or reversion from an irregular to a regular condition of the flower; in this instance there is an additional abnormality, since the pistil has proliferated, *i.e.* instead of carpels an inner flower has been formed which bears stamens, but inside the carpels again have produced vegetative structures, the bracts."

A fine sample of the Okapi (*Ocapia johnstoni*) has recently been acquired by the Hon. Walter Rothschild for his collection at Tring. The modelling has been entrusted to Mr. Rowland Ward.

In vol. lxxiv. part iii. of the *Zeitschrift für wissenschaftliche Zoologie*, Mr. R. Weinberg publishes the first of a series of articles on the brains of fossil vertebrates, dealing in this case with the small Tertiary perissodactyle

Anchilophus desmaresti. The brain of this mammal, it appears, although essentially primitive, exhibits all the characteristic ungulate features, with a marked approximation towards the modern perissodactyle type.

To the June number of the *Zoologist* Mr. Lydekker contributes a note on the probable use of the bilobed canine tooth of the giraffe and its allies, which forms the outermost of the four pairs of lower front teeth. It has been observed that, when browsing, a giraffe (unlike a deer or an antelope) strips the leaves from the branches without biting off the twigs, and it is inferred that the complex structure of the canine is designed to aid in this "combing" action.

THE June issue of the *Economic Proceedings* of the Royal Dublin Society is devoted to an account, by Mr. G. H. Carpenter, of injurious insects and other animals observed in Ireland during 1902. Special interest attaches to two excellent illustrations, one showing the caterpillar of the ghost swift moth (*Hepialus humuli*) feeding on the roots of wheat, and the other the injury done to young wheat by the maggot of the wheat-bulb fly (*Hylemyia coarctata*). Reference is made to the new fern-weevil (*Syagrius intrudens*) recently described by Mr. Waterhouse on the evidence of imported specimens found in the fern-houses at the Royal Botanic Gardens, Glasnevin.

THE Cairo Survey Department has recently published a preliminary description, by Messrs. Andrews and Beadnell, of the remains of a giant land tortoise (*Testudo ammon*) from the Eocene of the Fayum district. The especial interest of this form is its antiquity, which far exceeds that of all other known members of the group. Dr. Andrews thinks it probable that *T. ammon* is the ancestral form of the giant tortoises met with in several European Tertiary horizons, and that the existing African *T. pardalis* may be a small survivor of the group, to which the Siwalik *T. atlas* and *T. cautleyi*, and the existing *T. sumeirei* (the well-known giant tortoise of Port Louis) may also pertain.

IN the current number of the *Zeitschrift für physikalische Chemie* Prof. F. Kohlrausch gives a summary of the work which he has carried out during the last thirteen years on the electrical conductivity of saturated solutions of slightly soluble salts. In all forty-one such salts have been investigated, and the electrical conductivities determined at different temperatures. The data are to be used for the calculation of the solubilities of the various salts, and the numbers, which must be of considerable value to the analytical chemist, are to appear in a later paper.

THE results of a careful investigation by Dr. Freundlich on the precipitation of colloidal solutions by electrolytes are published in the current number of the *Zeitschrift für physikalische Chemie*. The capacity of different electrolytes for precipitating the colloids is dependent, in a large measure, on the valency of the ions, this capacity increasing with increase of valency. For colloids which show anodic convection under the influence of an electric current, the nature of the anion is without influence, whilst for those which exhibit kathodic convection the precipitation is independent of the nature of the cation.

AN interesting account of the behaviour of chlorine towards benzene under the influence of various catalytic agents is given by Mr. Slator in the *Journal* of the Chemical Society. With iodine chloride as catalytic agent, about 70 per cent. of the reacting chlorine is used up in the production of chlorobenzene, while the remaining 30 per cent. disappears in the formation of the addition compound benzene hexachloride. When tin tetrachloride and ferric chloride are employed as catalysers, the whole of the chlorine is used up in the substitution reaction. On the other hand, when chlorine interacts with benzene under the influence of light, addition only takes place.

FOR many years past it has been the practice of the Iron and Steel Institute to republish from time to time rare and interesting papers relating to the history and manufacture of iron and steel. With the permission of the council of the British Association, the institute has now added to the series the report presented by Bunsen and Playfair to the British Association at Cambridge in 1845, on "The Gases Evolved from Iron Furnaces, with Reference to the Theory of the Smelting of Iron." This research has long been looked upon as a model of the application of the methods of scientific investigation to the elucidation of industrial problems.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss Gayner Rowland; two Bristly Ground Squirrels (*Xerus capensis*) from South Africa, presented by Mr. H. J. Palmer; a Ruddy Ground Squirrel (*Xerus rutilus*) from Burao, East Africa, presented by Mr. Bennett Burleigh; a Brazilian Tapir (*Tapirus americanus*), a Red Brocket (*Cariacus rufus*) from Manáos, Brazil, presented by Mr. Charles Booth; a Grand Galago (*Galago crassicaudata*) from East Africa, presented by Captain C. Mylton Thornycroft; three Fat-tailed Desert Mice (*Pachyuromys dupresi*) from Egypt, presented by Dr. H. P. Keatinge; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, a Goldfinch (*Carduelis elegans*), European; a Red-bellied Waxbill (*Estrelda rubiventris*) from West Africa, a Yellow-bellied Liothrix (*Liothrix luteus*) from India, presented by Mrs. Halsey Ralph Ricardo; a Punjaub Sheep (*Ovis cycloceros*) from North-west India, two White-necked Cranes (*Anthropoides leucachen*) from Japan, four Demoiselle Cranes (*Anthropoides virgo*) from North Africa, purchased; a Burrhel Sheep (*Ovis burrhel*), a Sambur Deer (*Cervus aristotelis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1903 *c*.—A new ephemeris, calculated from new elements by Herr M. Ebell, is given in Kiel *Circular* No. 62. It extends to a later date than the one previously published by M. Fayet, and also varies slightly from that one. The following data are given for the four last dates included in the new ephemeris:—

Ephemeris 12h. (M.T. Berlin).

1903	α h. m. s.	δ ° ′	log Δ	Brightness
July 17	... 18 41 11	... +62 2·2	... 9·4324	... 14·6
„ 19	... 17 7 44	... +67 35·1	... 9·4553	... 14·2
„ 21	... 15 22 3	... +68 36·0	... 9·4906	... 13·1
„ 23	... 13 59 5	... +66 17·8	... 9·5327	... 11·7

The following observations of this comet are recorded in No. 3882 of the *Astronomische Nachrichten*.

Dr. Meyermann, using the Kreutz micrometer on a 6-inch comet-seeker, and Prof. Ambronn, with the Repsold heliometer, record that on June 23 the comet was 2′ in diameter and had a faint tail, whilst for June 24 the latter observer records that in difficult "seeing" a faint tail extending towards the south was seen.

Prof. Hartwig, using the Bamberg heliometer, records that on June 23 the nucleus was between the tenth and eleventh magnitudes, and the tail was of the divided form, having a mean position angle of 250°, whilst the coma was about 10′ in diameter.

Prof. Millosevich, observing at Rome with a 39cm. equatorial and a filar micrometer on June 23, recorded a 9·5 magnitude nucleus, and a very short tail, which extended in a S.S.W. direction.

SEARCH-EPHEMERIS FOR COMET 1896 V. (GIACOBINI).—A further instalment of the ephemeris of this comet is published in the *Astronomische Nachrichten*, No. 3881, by Herr M. Ebell.

The following is an extract from the ephemeris, which takes June 22·5, 1903 as the time of perihelion passage :—

Ephemeris 12h. (M.T. Berlin.)

1903	α h. m. s.	δ ° ′	log r	log Δ	Brightness.
July 16	1 59 36	+17 33·9	0·1697	0·1065	2·55
,, 24	2 20 51	+18 16·6	0·1749	0·0970	2·60
Aug. 1	2 40 51	+18 41·6	0·1814	0·0874	2·64
,, 9	2 59 22	+18 49·1	0·1889	0·0776	2·67
,, 17	3 16 7	+18 39·7	0·1975	0·0676	2·69
,, 25	3 30 50	+18 14·0	0·2068	0·0573	2·70
Sept. 2	3 43 15	+17 33·2	0·2168	0·0468	2·70
,, 10	3 53 10	+16 38·3	0·2272	0·0364	2·70

The continuation of this ephemeris indicates that, after the last-mentioned date, the comet will slowly decrease in brightness.

THE LIMITS OF UNAIDED VISION.—Lick Observatory *Bulletin* No. 38 gives an account of some interesting observations made by Mr. Heber D. Curtis, at Prof. Newcomb's suggestion, on the inferior limit of magnitude obtainable in naked-eye observations.

A preliminary examination of previous naked-eye catalogues showed that the mean magnitude of the faintest stars included in Ptolemy's Almagest was 5·38 on the scale of the Harvard Photometric Durchmusterung, whilst Houzeau in his "Uranométrie Générale" stated that stars of the sixth magnitude were constantly seen in a clear atmosphere, and those of magnitude 6·7 could be seen at intervals; the latter value corresponds to 6·40 on the Harvard scale. Gould, in the introduction to the "Uranometria Argentina," states that 6·5 was the average limit at Cordoba, but on exceptionally clear nights the seventh magnitude was possible. These two values are respectively equivalent to 6·16 and 6·71 on the Harvard scale.

In his own observations Mr. Curtis used two large blackened discs to screen off the diffused sky-light, these two discs being attached to the 12-inch telescope at a distance of 178 inches from each other, and the front one pierced by a circular hole half an inch in diameter, the rear one by a quarter-inch hole. By this arrangement he was able, on a night when a 6·53 magnitude star could be seen without using the discs, to see the following stars in the regions about T Virginis and T Ursæ Majoris respectively :—

Bonn DM. number	Declination ° ′	Magnitude	
3219	− 4 40	7·31 HP[1]	Seen quite easily.
3459	− 5 23	8·3 H[2]	Seen with considerable difficulty.
3463	− 5 37	8·1 H	Seen without difficulty.
1413	+60 18	8·3 H	Seen with difficulty.
1415	+60 13	8·5 H	Glimpsed at intervals; very doubtful.
1457	+59 30	8·2 H	Seen.

Mr. Curtis found that the screening off of the diffused light was even of more importance than knowing exactly where to look for the object.

AN ETHNOGRAPHICAL EXPEDITION TO BRITISH NEW GUINEA.

THERE are few areas of equal extent that present so many interesting sociological and cultural problems as British New Guinea. It is necessary these should be studied on the spot, and that, too, with as little delay as possible, for, even there, the remorseless activity of the white man is rapidly making itself felt.

We know there are various cultural provinces in British New Guinea which, in certain respects, are markedly distinct from each other; for example, we recognise districts that may, for the present, be conveniently distinguished by the geographical terms of Western, Fly River, Papuan Gulf, Central, South-Eastern, and North Coast, and some of these districts are capable of further subdivision. In most cases it is possible to tell within comparatively narrow limits the provenance of a decorated object by its form, technique, and the motive of its ornamentation. Although these general facts are well known to ethnological experts, there is still lacking an immense amount of detailed information of even these relatively superficial data that can be acquired only in the field. It is one thing to know what an object is and where it comes from, but it is much more important to understand the meaning of its form and decoration, and arm-chair musings, or even comparative study in museums, will be of little avail in this inquiry; on the contrary, they are liable to lead one astray.

It is becoming more and more recognised that the religion of primitive peoples is manifested in their arts and crafts, and that it is itself a reflex of their social condition. A student begins by being interested in patterns, is led into a study of comparative religion, and ends in sociology. In British New Guinea these several subjects have a peculiar interest. The decorative art is rich, varied, and distinctive. Concerning the religion very little is known; we are aware that true totemism occurs in the west, and it is probable that all stages, from animal reverence, through a hero-cult to an actual hierarchy of gods can be traced from the Netherlands boundary to the bight of the Papuan Gulf. The recognition of personal powers superior to man seems to be lacking in the Central District, and in the South-east District totemism again appears, and there is, or has been, a regard for the frigate bird, which in any case is probably not now totemic, but of the significance of this probable cult of the frigate bird we have at present not a particle of evidence. As to sociology, we have indications that British New Guinea possesses many varied and interesting aspects, and there is every reason to suspect a gradation in social structure will eventually be revealed that will illustrate some important phases of social evolution.

These are but one or two of the many promising fields of inquiry that British New Guinea affords to the ethnologist. At present we have but enough knowledge to appreciate the fact that there are these unsolved problems—the information being merely sufficient to emphasise our ignorance. It was his appreciation of this fact that led Major W. Cooke Daniels to organise an expedition to British New Guinea which will leave this country in August.

Major W. Cooke Daniels served in the United States Army during the Cuban campaign as Adjutant-General of Division. He has travelled extensively in British Guiana and elsewhere, and has consequently had much experience of travel and of organisation. He proposes to make observations in experimental psychology, and will undertake ethnological investigations. Dr. C. G. Seligmann, of St. Thomas's Hospital, was a member of the recent Cambridge Anthropological Expedition to New Guinea and Sarawak, and consequently has had considerable experience in anthropological field work. As the representative of the Cancer Commission on the expedition, he will investigate the question of the prevalence and incidence of tumours, especially those of a malignant type. He has care of the health of the expedition, and will help in the ethnological inquiries.

Dr. W. Mersh Strong, of Trinity College, Cambridge, will be responsible for the geographical and geological observations, and will undertake pathological and medical research as opportunity offers.

Preparations have been made for the taking of a very large number of photographs, including kinematograph records; this department is in charge of Mr. A. H. Dunning.

Major Daniels is sending to Australia for the expedition's use a schooner yacht fitted with auxiliary power; a sea-going launch is being taken out for river work. The expedition is fitted with a large amount of scientific equipment, so that all departments of anthropological research can be prosecuted. The majority of the surveying instruments have been lent by the council of the Royal Geographical Society. The Government Grant Committee has shown its appreciation of the expedition by giving a small grant, and the Royal Society has furthered its objects in various ways. The expedition is also recognised by the Cancer Commission.

It will be seen that the Daniels Ethnographical Expedition to New Guinea is thoroughly equipped, and we wish it the success it deserves.

[1] HP = Harvard Photometric Durchmusterung.
[2] H = Hagen's "Atlas Stellarum Variabilium."

ON A PROBABLE RELATIONSHIP BETWEEN THE SOLAR PROMINENCES AND CORONA.[1]

IN a previous number of this Journal (NATURE, vol. lxvii. p. 569, April 16) an account was given of the results which had been deduced from a minute investigation of the percentage frequency of prominences as determined from observations made by Secchi and Tacchini at Rome, and Ricco and Mascari at Catania and Palermo. It was there shown that the chief centres of prominence action, that is, the zones in which the greatest percentage frequency of prominences occurred, indicated movements in heliographic latitudes, the general tendency of these being in a direction towards the solar poles, and not towards the equator, as is the case with the spots. Attention was also directed to the fact that these centres of prominence activity were not restricted to a narrow zone like the spots, which only occur between the latitudes ±5° and ±35°, but that at times they were numerous in such high latitudes as ±80°, and even higher.

The present article contains an account of the results of a general survey that has been made regarding the connection between the changes of position of these centres of prominence action and the various forms of the corona as observed during total eclipses.

It has been suggested, and the idea is generally accepted, that the various forms of the solar corona are intimately connected with the variation in the spotted area of the sun's surface. Thus, generally speaking, at about the epochs of sun-spot maxima, the corona is apparently very irregular in shape, there being little or none of the exquisite tracery at the sun's poles which is so evident at the epochs of sun-spot minima, while the streamers are less confined to mid-solar latitudes and the region near the equator than they are at the minima.

The facts that sun-spots do not appear nearer the poles than latitudes ±35°, and that large coronal streamers and prominent rays are sometimes visible in much higher latitudes than these—in fact at times near the poles of the sun, and consequently outside the regions of spot activity—suggested that the occurrence of prominences, very important factors in the mechanism of the solar atmosphere, might be closely connected with them.

In the present general inquiry, the forms of the coronas that have been observed since the year 1857 have been divided into three main types, and this classification, which is not new, is one into which most of the coronas, with the exception of two, namely 1865 and 1885, can be easily placed. Since the forms of coronas are dependent chiefly on the positions of the coronal streamers, the three different types here adopted refer in the main to the positions of these streamers in relation to the solar equator and poles.

In the first, or "polar" group as it has here been called, since streamers are found near the solar poles, all those coronas are included which seem to have no regular form. The typical features of this group are that the polar rifts are absent, being replaced to a great extent by streamers at, or very close to, the poles, and the streamers are numerous in nearly all solar latitudes; also there is no definite equatorial extension. To this class the following coronas belong, 1860, 1870, 1871, 1882, 1883, and 1893.

In the third, or "equatorial" group, since the streamers are in lower latitudes, and consequently more equatorial, the form of the corona is very regular. The polar rifts have a great spread in latitude and are well defined, while the large streamers are restricted to the regions near the equator; in fact, the great equatorial extensions are best seen in this type. This form generally takes the shape of a "wind vane," and is often referred to as such. The coronas which come into this category are those of 1867, 1868, 1878, 1889 January, 1889 December, 1900 and 1901.

The second group of this classification may be termed the "intermediate" type, as the streamers are about half way or intermediate between the poles and the equator. In this group the polar rifts are present, but they are not so extensive in latitude as in the "equatorial" class. The coronal streamers also approach nearer the polar regions than in the "equatorial" class, but not so close as in the "polar" group, while the equatorial extensions are not in such great evidence. Generally speaking, this form of corona is due to a large streamer in each quadrant, which gives the corona the appearance of a square, hence the name "square corona," which has been often used.

The coronas which fall under this heading are 1858, 1869, 1874, 1875, 1886, 1887, 1896, 1898. It may be stated

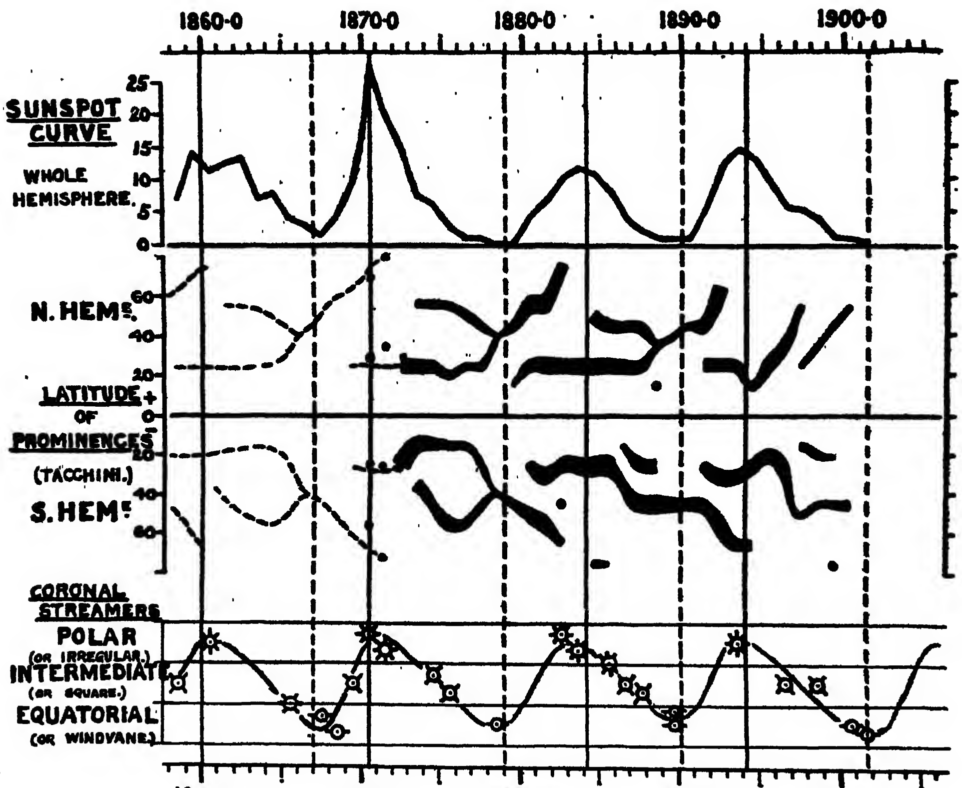

FIG. 1.—Curves showing the relationship between the different forms of the corona, the positions of the centres of action of prominence phenomena and the general sun-spot curve. The continuous and broken vertical lines indicate the epoch of the maxima and minima respectively of the last mentioned curve.

[1] Abstract of a paper recently communicated to the Royal Astronomical Society by Dr. William J. S. Lockyer.

that the "polar" and "equatorial" coronas are always followed by "intermediate" types, the order being polar, intermediate, equatorial, intermediate, polar, &c.[1]

The "intermediate" type may sometimes approach in form a "polar" or an "equatorial" type, according as the epoch of the occurrence of the eclipse occurs nearer or further from the epochs of occurrence of polar prominences.

Further, the "intermediate" type preceding a "polar" type will differ to some extent from one immediately following a "polar" type, because the latitudes of the centres of prominence action in each case are different, as can be seen from the accompanying figure.

Two coronas which have not yet been classified are those of 1865 and 1885. The former of these is of a type between the "intermediate" and "equatorial," while the latter falls between the "polar" and "intermediate" groups. These have been inserted on the dividing lines in Fig. 1. In classifying the coronas into the above groups, I have been greatly assisted by Mr. W. H. Wesley, to whom I wish to express my best thanks.

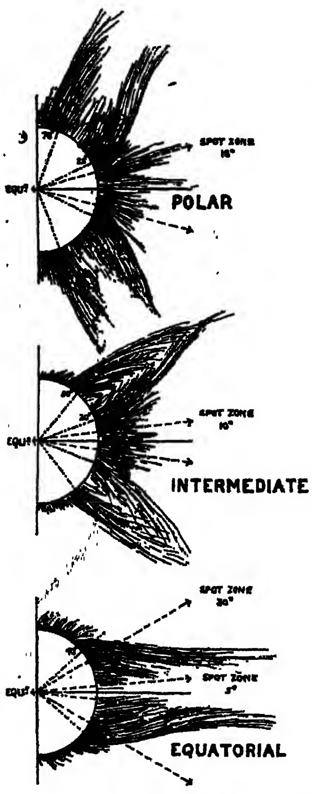

FIG. 2.—Diagram showing by radial lines the positions of the centres of prominence action and their relation to the chief features of individual coronal streamers and to the general form of the corona. The positions of the sun-spot zones are also indicated.

The first natural and crucial test to apply, in order to determine whether there was a connection between prominences and the different forms of the corona, was to inquire whether the coronal streamers were situated nearest the solar poles, at those times when the prominences were most numerous in those regions.

The comparison for this test showed that the only five "polar" coronas recorded since the year 1869, when prominence observations were commenced, occurred at those epochs when the prominences attained their highest latitudes.

This satisfactory result indicated a very probable cause and effect between prominences and the coronal streamers, for the region considered was quite outside the zone of the spots, and therefore independent of them.

It was next found that the other two types of coronas were closely associated with the number and latitudes of the centres of prominence action. Thus the "equatorial" type only occurred when there was *one* definite centre of prominence action in each hemisphere, while the "intermediate" type has been recorded at those times when *two* centres of action in each hemisphere were in progress, neither of which were in very high latitudes.

The accompanying illustration (Fig. 1) shows the relationship between the sun-spot curve for both hemispheres together, the latitudes of the centres of action of the solar prominences for each hemisphere, explained in detail in a previous number of this Journal (NATURE, vol. lxvii. p. 569, April 16), and the times of occurrence of all the eclipses that have occurred since the year 1857. When two eclipses of a similar type occur in the same, or two successive years, they have been inserted either one above the other or obliquely, respectively, to avoid overcrowding. A curve is also drawn through the different types showing their relation to the sun-spot curve.

Since the systematic prominence observations only commenced in the year 1872, the dotted portions of the curves previous to that date are intended only to give a rough idea of the variations as based on a general repetition of the observations of 1872 to 1885.

Fortunately for the present inquiry, Respighi made some very valuable prominence observations during the years 1870, 1871, and 1872, which are sufficiently numerous to indicate the positions of the centres of prominence activity for these years. These showed that during the years 1870 and 1871 there were two well-marked prominence zones in each hemisphere, and that the latitude of one of the zones was very high. The positions of these zones are indicated in the accompanying figure by the small dots against these years, and they agree well with the suggested curves representing the probable conditions as might have been expected from subsequent observations.

The different types of corona are plotted in three different horizons in the order "polar," "intermediate," and "equatorial," and the symbols adopted for each, namely, small circles with 8 rays for the first, 4 rays for the second, and 2 rays for the third, are inserted at the epochs of their occurrence according to the general time scale for all the curves. The continuous and broken vertical lines denote the epochs of the sun-spot maxima and minima, as determined from a discussion of spots recorded on both hemispheres of the sun.

At the first glance it will be observed that the three types of the corona, as seen from the curve drawn through them, follow the sun-spot curve very closely, that is, that at about the times of the maxima of sun-spots, the "polar" type is present; at the minima, the "equatorial" type; and at the intervals between these, the "intermediate" type. Although the sun-spot curve thus affords a means of predicting in a general manner the epochs about which any of these types will occur, such a small restricted zone which the spots occupy excludes the idea of their presence being responsible for such widely distributed coronal phenomena.

The prominence curve, on the other hand, not only provides one with a more accurate method of forecast, but such phenomena *can account for the general changes of position and form of the coronal streamers.*

By examining the prominence curves in relation to the three different types of coronas from the year 1869, this connection is seen to be very close. Thus, during the years 1870 and 1871 there were two centres of prominence action in each hemisphere, one of which was in high latitudes, and the coronas for that period were of the "polar" type. From the year 1872 to 1877 there were two centres of prominence activity in each hemisphere, both in comparatively low latitudes, and the two eclipses during the period, namely, 1874 and 1875, were of the "intermediate" type. The next eclipse, 1878, occurred when only one centre of action was in existence, and the form of the corona was of the "equatorial" type.

As these centres of prominence action reached their extreme polar limits (about $\pm 80^\circ$), and a new centre had in the meanwhile commenced in lower latitudes ($\pm 25^\circ$), the eclipses of 1882 and 1883 were of the "polar" type.

The next two eclipses, of 1886 and 1887, which were "intermediate," occurred when there were again two centres of prominence action in each hemisphere, but none near the poles. When the centres became single, as they did in the years 1889, 1890 and 1891, the two coronas observed in the year 1889 were of the "equatorial" type. With the movement of these centres to high latitudes in the years 1892, 1893, 1894, the eclipse of 1893 was of the "polar" type.

The two eclipses of 1896 and 1898, which were "intermediate" in type, occurred when there were two chief centres of prominence action, while the two most recent eclipses of 1900 and 1901 were good examples of the "equatorial" type, and were concurrent with only one centre of prominence activity in each hemisphere.

If the eclipses observed between 1856 and 1870 be compared with the dotted prominence curves for the same

[1] It may be here remarked that the "intermediate" type between an "equatorial" and "polar" type has only once (1869) been recorded during the period here under investigation, and this is due to the absence of observed eclipses during the two short available periods since that date, namely, 1879–81 and 1890–92.

period, it will be seen that a similar connection seems to exist between the latitudes of the centres of action of the prominences and the three types of coronas.

The investigation seems to indicate that it is the *sum total of prominence action* in the different zones which produces the large coronal streamers, and not any particular prominence at any particular moment; it is for this reason that the form of the corona is not a fleeting phenomenon changing every minute or hour, but one lasting over several months, and sometimes as much as a year or more. That the general form of the corona does undergo comparatively slow changes is borne out, to a great extent, by the similarity of coronas which are observed at eclipses which occur close together, such as those in 1900, 1901, the two eclipses in 1889, &c.

It is of great interest briefly to note the connection between the centres of prominence action when either two or one of them exist in each hemisphere. In the first place a well-defined large coronal streamer apparently originates, as many photographs indicate, not from disturbance at the *centre* of its base, but near the two ends. Such a streamer is generally made up of groups of incurving structure, termed previously "synclinal" groups, and this structure is, in many cases, very distinct. When there are *two* centres of prominence action in one hemisphere, the coronal disturbances resulting from each trend towards each other, and constitute a large streamer with an apparent "arch" formation. If the two centres of prominence action exist in comparatively mid-latitudes, one large streamer is formed in each quadrant, and the form of the corona is of the "intermediate" or "square" type.

When one of the centres is near the region of the poles and the other in comparatively low latitudes, the tendency is still for the two disturbed coronal regions to trend towards each other, but they constitute either a large streamer of an "arch" formation nearer the solar poles with a very extended base, or two separate streamers which combined have a fish-tail appearance.

With *one* centre of action of prominences in each hemisphere, the resulting coronal disturbances in both hemispheres curve towards the solar equator, and form apparently a large equatorial streamer; the "equatorial" type of corona is here formed.

The accompanying sketches (Fig. 2) illustrate in diagrammatic form the general relationships between the latitudes of the spot zones, the latitudes of the centres of action of the prominences, and the suggested resulting positions and origin of structure of the coronal streamers for each of the three types of coronas here discussed. It will be noticed that in the case of the "polar" and "intermediate" types, when the sun-spots are numerous, the zones in which they occur have apparently little connection with the coronal streamers. When the latitudes of the spot zones do approximate more nearly to the bases of the coronal streamers, as in the "equatorial" type, and might be considered as being the origin of their existence, the spots at these epochs are near a minimum, that is, are very few and small in size, and have the least power of action.

WILLIAM J. S. LOCKYER.

SOME PRESENT AIMS AND PROSPECTS OF MATHEMATICAL RESEARCH.[1]

IT may be doubted on the whole whether any completely scientific and permanent dividing lines for the classification of modern original work of pure and applied mathematics can be drawn.

The nearest approach is perhaps an arrangement according to motive. Thus a first class may be constituted of those investigations which aim at discovering and establishing the foundations of the subject, and obtaining rigorous proofs of theorems already known; such work as that which Peano and Russell are doing in their symbolic notation for the general principles of mathematics, or Pieri and Veronese for the axioms of geometry, or Picard for the existence theorems of differential equations, or Vallée-Poussin for the differentiation of definite integrals.

[1] From an address by Mr. E. T. Whittaker on "Some Present Aims and Prospects of Mathematical Research," delivered before the University College Mathematical Society on June 25.

Although the primary aim of such papers is that of imparting a strict logical rigour to the theory discussed, yet the most surprising and unexpected new results are constantly arising in them; as an instance, I may mention Fano's discovery of a space which consists only of 15 points, and which satisfies all the conditions for an ordinary projective space except the condition that each part is to be distinct from its harmonic conjugate; or the remarkable result that a projective geometry of two dimensions cannot be obtained without the supposition that the two-dimensional space is contained in a three-dimensional space; or the well-known theory of Fourier series and integrals which can represent different analytic functions in different parts of their domain of existence. It is a notable fact that this type of research seems peculiarly congenial to the mind of the Latin races. Undoubtedly much work of the kind has been done in Germany during the nineteenth century, but the honour of its foundation must be assigned to Cauchy, and its home has always been in France and Italy. In this country it has never thoroughly taken root, perhaps because, as someone said, the Englishman cannot distinguish between a proof and an appeal to the jury. In America, however, a considerable amount of attention is now given to the subject by such writers as Moore, Osgood, Bôcher, and Huntington.

A second class of research can be formed from those which are directly provoked by some observed phenomenon of nature, researches of which the immortal type is Newton's discovery that if the planets move in ellipses with the sun in one focus, it must be because they are attracted to the sun with a force which varies as the inverse square of the distance.

In work of this kind our country has always borne a distinguished share; the greatest achievements of the English school of mathematical physicists must all be included in it, and even at the present time no paper excites so much interest among us as one which gives a mathematical explanation of the Zeeman effect or the second law of thermodynamics.

A third class of investigations may be made to consist of those in which the motive is not in some external phenomenon, but in what may be called the internal expansive force of the subject itself, the inherent capability of extension, which is latent in every theorem of mathematics, the desire of the mathematician who has solved the quadratic equation to solve the cubic and quartic, and then either to solve the quintic or to show that it cannot be solved by radicals.

This, which is by far the largest of the three classes, admits of several subdivisions, according as the successful issue of the work is due mainly to the author's geometrical imagination, as in the writings of Cremona and Chasles, or to his power of algebraical analysis, as in much of the work of Jacobi and Cayley, or to his having brought to bear on the subject a novel set of ideas, as, for instance, in Fuchs's papers on linear differential equations, or to what may be called pure constructive intuition, which does not depend on the extension and generalisation of preceding results, as for instance, Euler's expression for the gamma-function as an infinite product, or his solution of the many types of differential equations.

The second of these subclasses, namely, that in which the successful management of highly complicated symbolic work is the most prominent feature, has flourished perhaps more than any other branch of non-physical mathematics in our own country.

It may be questioned whether this is not in part a consequence of the traditional English mode of training, which includes far more working of hard examples than is customary abroad, and thereby gives the mathematician that algebraical power which comes of much practice: but no one can see such work as that of Cayley or Forsyth without feeling that it is largely due to an inherent algebraic power with which our distinguished fellow-countrymen have been endowed. The introduction of new algorithms and new concepts is, on the other hand, a German characteristic; a notable instance is furnished by the invariant-theory, which, after its first development by Cayley and Salmon on purely algebraical lines, was transformed by Aronhold's introduction of the symbolic notation. The *Mengenlehre* of Cantor, the Ausdehnungslehre of Grassmann, numerative geometry and the theory

of algebraic numbers, are instances of subjects the inception of which we owe to the Germany of the nineteenth century.

While, as we have already remarked, the English have shown a considerable interest in some branches of research, it is often said, and I think with truth, that our record in the history of modern mathematics is not worthy of our place among the nations. It is, at any rate, a fact that a considerable number of men spend the greater part of their student life in the special study of mathematics, and after a successful college career are appointed to teaching posts which leave them a fair amount of leisure for the pursuit of their chosen subject, and that, nevertheless, their life is barren of contributions to learning. This state of things, which we must admit to be much more general in this country than on the Continent, is, perhaps, the gravest feature in the situation at present, and it becomes deeply interesting to attempt to trace its course.

The explanation which I personally favour places the origin of the evil back in student days, and in our methods of instruction. The most casual reader of text-books cannot fail to be struck by the fact that English text-books treat their subjects in much greater detail than is customary on the Continent; innumerable side-issues are raised, trifles are elaborated, and examples are multiplied a hundredfold. Moreover, topics which have now become comparatively unimportant, or even positively obsolete, are always retained, and each text-book differs from its predecessor only in a further increase of prolixity.

The result is that even the best men cannot, in a student course of many years, wade through this mass of material to the frontier of existing knowledge, and the unfortunate student finds his college career over and his teaching life begun before he has gone anything like far enough to begin independent research.

I can scarcely conceive a greater benefit to the study of mathematics in this country than a series of short text-books holding closely to the main lines, casting away the rubbish and the trifles, and carrying a student to the furthest boundary of learning in a three years' university course.

Although the evil relates chiefly to college text-books, it would not be difficult to mention branches of higher learning the progress of which has been arrested for a long period simply by the publication of unreadable accounts of them.

In order that our research may be the worthy centre of a life-work, it is needful to have not merely the equipment of a full knowledge of the past, but also a clear and well-defined idea as to which are to be considered the chief and which the minor objects of investigation. For the next worse thing to doing no research at all is to spend one's time on matters that are of very little consequence.

This point is all the more important because there is every indication that we are now at a critical point in the history of mathematics, and that the twentieth century will see progress in somewhat different directions from those which characterised the last half of the nineteenth.

Let me recall the fact that, from the time of Newton to the death of Cauchy in 1857, the main progress of mathematics was in the realm of analysis—the science which is based on Newton's infinitesimal calculus, and which was enriched by all the greatest masters, Euler, Lagrange, Laplace, D'Alembert, the Bernouillis, Taylor, Legendre, Fourier, Gauss, Abel, Jacobi, and Cauchy.

The latter half of the nineteenth century saw, however, a notable change. As in the hands of these giants even the inexhaustible mine of analysis seemed to be worked out, new subjects came into prominence, such as invariants, the theory of groups, the Mengenlehre, analysis situs, quaternions, and non-Euclidean geometry; the theory of functions developed itself on lines quite foreign to the older analysts, and the demand for rigorous proofs led many even of those who remained in the domain of analysis, as Du Bois Reymond and Pringsheim, to devote themselves rather to a careful investigation of the foundations than to an extension of the superstructure. Now, however, we seem to be on the threshold of a change. The branches of mathematics the introduction of which we owe to the last generations of German mathematicians are already beginning to show signs of exhaustion—by which I mean that further work in such a subject as the invariant-theorem along the present lines does not promise to yield any great increase of mathematical power; the process of underpinning the edifice has now been, to a great extent, accomplished, and the work of upbuilding can be recommenced, while the interest of the theory of functions has largely passed over into topics of a distinctly analytical character, such as the theory of automorphic functions, the theory of expansions convergent within a given region, and the theory of summable series.

All the indications seem to point to the conclusion that pure mathematics is in the process of its natural evolution returning to the old path, and that a new phase of advance in the analysis of differential equations and functions is about to come upon us.

But though the same, it will be changed; the work of the last fifty years has given rise to ideas and methods the application of which must necessarily extend the older subjects in altogether new directions, and perhaps lead to an era worthy to be compared with that of Euler and Lagrange.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Joule studentship, founded "to assist research, especially among younger men, in those branches of physical science more immediately connected with Joule's work," will shortly become vacant through the termination of the tenure of Dr. Ulrich Behn, who was nominated by the K. Akademie der Wissenschaften of Berlin in 1901. On this occasion the nomination of a student rests with the president and council of the Royal Society, who will make their selection in October next. The studentship is of the value of 100*l*. in all. Information may be obtained from the assistant secretary of the Royal Society.

WE regret to see the announcement of the death of Sir Joshua Fitch at the age of seventy-nine. The country has thus lost one of its foremost authorities on educational theory and practice. Sir Joshua Fitch was for thirty-one years connected with the Education Department, and the wide and varied experience which he acquired give exceptional weight to his views on educational subjects, expressed in many articles, books and addresses. Since his retirement from official life in 1894, he has taken an active part in the formation of sound public opinion upon educational questions. He recognised that the important point to bring before the people was "that education ought to be a national concern, that it should not be left entirely to local, or private, or irresponsible initiative." This principle must be accepted before any substantial provision will be made for educational progress. Sir Joshua took an active part in the reorganisation of the University of London as a teaching university, and throughout his career identified himself with movements which had for their object the coordination and development of the educational forces of the country.

OF the Education Vote of 11,249,806*l*. agreed to by Committee of the House of Commons last Thursday, only half a million belongs to secondary education. In the course of a speech made in introducing the vote, Sir William Anson expressed the fear that the traditional educational work was being destroyed, and was not being replaced with anything of a really substantial character. He was especially alarmed at the condition of the smaller grammar schools. "In these schools much attention is now being given to science, with results that are not altogether satisfactory. The classical languages are almost disregarded, and history and geography are neglected." Mr. Balfour spoke to much the same effect in the speech at the Allied Colonial Universities dinner which appears in another part of this issue. The suggestion is that science is not such a good educational instrument as the study of dead languages. It does not need much consideration to see that these conclusions are unsound. For centuries our grammar schools have been training grounds for teachers of Greek and Latin, and it would be strange if efficient methods had not been evolved. Every encouragement has been given to the humanities both in school and university, and the masters who have controlled the curriculum or guided the studies have been, with rare exceptions, men distinguished for

their attainments in classical fields. It is scarcely too much to say that few of these men have welcomed the introduction of science into the school curriculum. But, for the sake of recognition by county councils, and the consequent grants, science has been given a place in grammar schools as a paying guest. In many cases the headmasters know nothing of science, and care less; and the teachers in charge of the science work receive little encouragement to do anything but push on promising pupils to scholarship examinations. It is, of course, impossible to discover the educational value of scientific studies under these conditions, when no provision has been made for the supply of qualified teachers, and while the idea still prevails among many masters that text-books and lectures are the most important means of imparting scientific knowledge. It would be strange if the results of such teaching were satisfactory. If Mr. Balfour and Sir William Anson will examine the matter a little more closely, they will see that no fair comparison can yet be made between the merits of classical and scientific studies. Everything depends upon the method by which the subject is taught, and the spirit which inspires the teacher.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 14.—"The 'Elasmometer,' a New Form of Interference Apparatus for the Determination of the Elasticity of Solid Substances." By A. E. H. **Tutton**, D.Sc., F.R.S.

The apparatus is designed to measure the amount of bending suffered by a thin plate of the substance investigated, when supported near its ends against a pair of platinum-iridium knife-edges, under a known weight applied at its centre. It consists of an elaborate apparatus for the support and adjustment of the plate and knife-edges; a measuring microscope, reading in two rectangular directions by a new method to the thousandth of a millimetre, for measuring the dimensions of the plate *in situ*; a specially constructed form of balance, one end of the beam of which carries an agate point, through which a pressure is applied under the centre of the plate equal to the weight in a pan suspended from the other end; a delicate control apparatus, which only permits the weight to operate extremely slowly; an interference apparatus, of which the two reflecting surfaces concerned in the interference are (1) the lower surface of a colourless glass disc supported on a tripod in rigid connection with the knife-edges, and (2) the upper surface of a smaller black glass disc forming the top of a counterpoised rocker, arranged to move with the centre of the plate and thus to transmit its motion. The amount of diminution in the thickness of the air film between the two glass surfaces, consequent on the bending of the plate, is given by the number of interference bands which pass the centre of reference, as seen in the micrometer eye-piece of the observing apparatus, multiplied by half the wave-length of the G or F hydrogen light which is employed. The optical apparatus of the dilatometer previously exhibited is utilised for the transmission of the hydrogen light to the interference apparatus, and as observing apparatus.

June 18.—"On the Discharge of Electricity from Hot Platinum." By Harold A. **Wilson**, D.Sc., B.A., Fellow of Trinity College, Cambridge. Communicated by C. T. R. Wilson, F.R.S.

This paper contains an account of a series of experiments on the discharge of electricity from hot platinum wires. The main object of the investigation was to determine the influence exerted by the nature of the gas in which the wire is immersed.

It was found that the presence of traces of hydrogen in the wire enormously increases the leak of negative electricity from it. By taking precautions to remove hydrogen the negative leak was diminished to one part in 250,000 of its usual value. The presence of traces of phosphorus pentoxide was found enormously to increase the negative leak, and it is known that alkali salts have a similar effect. The results obtained lead to the conclusion that the negative leak is due to the presence of traces of hydrogen, or possibly other substances, in the wire.

With a particular wire in air, the small negative leak remaining when impurities have been got rid of, as far as possible, only falls off very slowly with time, and its variation with the pressure of the air, the potential difference, and the temperature can be measured.

It is shown that the variation of the negative leak with the air pressure and potential difference is due to the ionisation of the air by collisions of the negative ions leaving the wire with the air molecules. If the P.D. used is too small to produce ionisation by collisions, the leak is independent of the air pressure.

The variation of the negative leak with the temperature is investigated, and a formula which represents it is deduced from thermodynamical considerations.

The negative leak in hydrogen at various pressures is measured and found to increase proportionally to the pressure at low pressures. It is shown that the negative leak depends on the amount of hydrogen occluded by the wire. The following table gives the negative leaks at 1400° C. at several pressures in hydrogen:—

Pressure.	Current per sq. centim.
133·0 mm.	$1{\cdot}0\times10^{-3}$ ampere.
0·112 ,, ...	$1{\cdot}2\times10^{-5}$,,
0·0013 ,, ...	$2{\cdot}0\times10^{-7}$,,
0·0 ,, ...	$1{\cdot}2\times10^{-10}$,,

The energy required for the production of a gram molecular weight of negative ions is found to have the following values:—

(1) Thoroughly clean wire in air or vacuum	155,000 calories.
(2) Cleaned wire in air or vacuum.	131,100 ,,
(3) Wire in H_2 at 0·0013 mm. ...	120,000 ,,
(4) ,, ,, 0·112 ,, ...	85,900 ,,
(5) ,, ,, 133·0 ,, ...	36,000 ,,

The paper also contains measurements of the positive leak. It is shown that there is no positive leak appreciable on a galvanometer from a clean wire in a vacuum. In air or hydrogen there is a positive leak, which increases with the gas pressure, and which is probably due to ionisation of the gas molecules in contact with the hot platinum.

It is probable that a pure platinum wire heated in a perfect vacuum would not discharge any electricity at all, either positive or negative, to an extent appreciable on a galvanometer.

"Upon the Bactericidal Action of some Ultra-violet Radiations as Produced by the Continuous-current Arc." By J. E. **Barnard** and H. de R. **Morgan**. Communicated by Sir Henry Roscoe, F.R.S.

The experiments described were carried out with the object of determining the effect on the vitality of bacteria, as the result of exposure to the arc spectra of carbon and of various metals.

The organisms experimented with have been the *Bacillus coli communis*, *B. prodigiosus*, *B. subtilis*, *Micrococcus tetragenus*, *Staphylococcus aureus* and *Bacillus tuberculosis*.

The conclusion arrived at is that the bactericidal action of light is almost entirely due to the action of those radiations in the ultra-violet region of the spectrum which are included between the wave-lengths 3287 and 2265. It is, therefore, necessary that any source of light used as a bactericidal agent should be rich in these rays.

Royal Meteorological Society, June 17.—Captain D. Wilson-Barker, president, in the chair.—Dr. W. N. **Shaw**, F.R.S., read a paper on the meteorological aspects of the storm of February 26–27. Between sunset of February 26 and noon of February 27, the British Isles were visited by a storm of unusual severity. Its most impressive characteristic was the amount of damage done to trees and buildings by gales from the south or south-west, particularly in the neighbourhood of Dublin, where very large numbers of trees were uprooted, and in Lancashire. Gales or strong winds were also experienced in many parts of the British Isles. Dr. Shaw exhibited lantern slides showing the path of the barometric minimum and the area over which the destruction extended. He also put forward some general considerations about barometric depressions and storms, dealing more especially with the distribution of winds and

the velocity of travel, and concluded by making some remarks on self-recording instruments and their management.—A paper by Mr. J. **Baxendell**, on the Dines-Baxendell anemograph and the dial pattern non-oscillating pressure-plate anemometer, was read by the secretary. The Dines pressure-tube anemometer is now the accepted standard instrument for recording wind movement, but it does not record the direction of the wind. Mr. Baxendell has endeavoured to overcome this drawback, and in this paper he gives a description of the combined velocity and direction anemometer which he has designed for the Fernley Observatory at Southport. In addition, he has designed a non-oscillating pressure-plate for showing on a dial the maximum pressure of the wind. By using a combined "head" or vane for the Dines anemometer, Mr. Baxendell has been able to arrange for the new instrument to record (1) the velocity, (2) the direction, and (3) the maximum pressure of the wind.

Linnean Society, June 18.—Prof. S. H. Vines, F.R.S., president, in the chair.—New Chinese plants, by Mr. S. T. **Dunn**. In this, descriptions of more than seventy new species are given, founded on specimens collected chiefly in Yunnan by Dr. A. Henry and Mr. E. H. Wilson.—The germination of the seeds of *Davidia involucrata*, by Mr. W. Botting **Hemsley**, F.R.S. The fruit has an exceedingly hard, bony endocarp or "stone," enclosing usually a number of seeds, and causing wonder how they can free themselves for germination. Under the influence of moisture, a portion of the back of each cell (carpel) separates and falls away in the form of a valve or shutter, revealing a portion of the seed. The radicle soon begins to grow, and in due time reaches the ground, when the upper part of the plantlet frees itself and commences an independent existence.—Rudimentary horns in horses, by Dr. G. W. **Eustace**. Two thoroughbred horses showed bilateral osseous prominences, casts of which were shown; in both the left or near boss is the larger. The occurrence of these is extremely rare, but the pedigree of all known instances being traced back, it is found that they are all descended from the Darly Arabian, bought at Aleppo, and shipped to England in 1705; further, all are descended from Eclipse. The only reference to this phenomenon is that noted by Darwin, "Variation of Animals and Plants," vol. i. p. 52. The author shows that these bosses are not mere exostoses due to disease, and draws the conclusion that they are instances of the reappearance, in a rudimentary condition, of structures which once existed in a functionally perfect condition.—Scottish fresh-water plankton, part i., by Mr. W. **West** and Prof. G. S. **West**. The paper deals with plankton-material from lochs in different parts of Scotland and the Outer Hebrides. The Scottish plankton is found to differ considerably from that of the western part of continental Europe; it is remarkably rich in Desmids, which are of a distinctly western type, and the most abundant are species of Staurastrum. The scarcity of free-swimming Protococcoideæ is striking, but Diatoms are fairly represented. A noteworthy feature is that both Diatoms and Desmids display long spines or processes; this excessive development is ascribed by the authors to the assumption of a purely free-swimming habit.—On the anatomy of the leaves of British grasses, by Mr. L. **Lewton-Brain**. The paper is the result of testing the classification of leaf-structure devised by Prof. Marshall Ward. Four main types are recognised:—(1) leaves in which the upper surface is flat or nearly so; (2) the upper surface marked by distinct though not very high ribs; (3) the upper surface marked by very distinct and high ribs; and (4) the upper surface reduced to a mere fold in an almost solid leaf.

Geological Society, June 24.—Sir Archibald Geikie, F.R.S., vice-president, in the chair.—On a transported mass of Ampthill Clay in the Boulder-clay at Biggleswade (Bedfordshire), by Mr. Henry **Home**. Under 10½ feet of soil and Boulder-clay, the Ampthill Clay was penetrated for 67 feet, resting on Chalky Boulder-clay, fine silty clay, disturbed Gault, and Lower Greensand. The clay is lithologically identical with the Ampthill Clay with its selenite-crystals, and contains *Ammonites excavatus*, often covered with Serpulæ, but no abundant examples of *Ostrea deltoidea*. The boulder was probably an outlier, situated in Oxford Clay at a level high enough to be ploughed into by the agent which formed the Glacial Drift.—The Rhætic and Lower Lias of Sedbury Cliff, near Chepstow, by Mr. Linsdall **Richardson**. The chief portion of the cliff-section described has a direction north-east and south-west; the dip of the beds does not exceed 3° to the south-south-east.—Notes on the lowest beds of the Lower Lias at Sedbury Cliff, by Mr. Arthur **Vaughan**. The two chief points of interest of this section are, the relation of the basal conglomerate to the Cotham Marble and White Lias of neighbouring districts, and the examination of the faunal sequence, with a view of testing the absolute value of ammonite-zones. A diagram is given showing the times of appearance and disappearance, the abundance or rarity, of several fossils within and below the zone of *Ammonites psilonotus*, and on account of the beginning of five forms at a given horizon and the disappearance of several forms immediately below it, this level is chosen as the base of the zone of *A. psilonotus*, rather than the point of appearance of *A. planorbis*, 4 feet higher up. It is hoped that the construction of similar diagrams will be of use in testing the value of a series of ammonite-ages as divisions of relative time.

DUBLIN.

Royal Dublin Society, June 16.—Prof. J. M. Purser in the chair.—Prof. T. **Johnson** and Miss M. C. **Knowles** gave an account of the contents of the British herbarium of the late H. C. Levinge, which had been given to the National Museum in Dublin. The collection contains specimens of nearly all the species of flowering plants and ferns recorded for Ireland; it is especially rich in Westmeath plants, and supplies many additions to the records of Irish topographical botany. Mr. Levinge's herbarium of ferns, British and foreign—4000 sheets—had been previously given to the museum.—Prof. J. A. **McClelland** read a paper on ionisation in atmospheric air. This paper deals with the amount of ionisation in free atmospheric air, and the variations of the ionisation at different times. The largest values have been obtained after several hours' continuous rain, which would agree with the known radio-activity of freshly fallen rain. On the other hand, very small values of the ionisation have been found after slight showers, probably because the ions have been removed from the atmosphere by the condensation on them of water vapour.—Dr. Henry H. **Dixon** showed a model for illustrating the part played by the mesophyll cells in transpiration. The model consists of a funnel closed above by two membranes, between which is a lenticular space containing a sugar solution. The funnel and its stem are filled with water, and, when set in an upright position, are supplied with water through a capillary tube. The motion of water in this tube is made apparent by microscopically observing a precipitate suspended in it. In the paper the working of the model is explained, and it is pointed out that the tension set up by evaporation from the surface of the leaf-cells is transmitted, through the solvent in them, to the water in the conducting tracts of the plant, while at the same time the dissolved substances exert an osmotic pressure and keep the cells turgid. The paper also contains the description of an experiment by which the solvent of osmotic cells may be subjected to tension while at the same time the pressure exerted by the solute is apparent.—Prof. A. W. **Conway** read a paper on a new foundation for electro-dynamics; a modification of the scheme of Helmholtz was proposed in it, the scalar and vector potentials being multiplied by a factor showing Döppler effect.—Mr. J. T. **Jackson** described a new method of producing tension in liquids; how ordinary tap water, just as drawn from the city supply mains, had been subjected to a tension of 38lb. per square inch. Advantage was taken of the principle underlying the working of the common filter pump, Venturi water-meter, spray distributor, &c. The water was forced through a glass tube constricted at one point, and the pressure at the constriction was estimated to fall below two and a half atmospheres negative.

Royal Irish Academy, June 22.—Prof. R. Atkinson, president, in the chair.—On the synthesis of glycosides—some derivatives of arabinose, by Prof. Hugh **Ryan** and Mr. George **Ebrill**. Following the method employed by Ryan

for the synthesis of glycosides (*Jour.* Chem. Soc., 1899, p. 1054; 1901, p. 704), the authors have obtained from the acetochloroarabinose previously prepared by Ryan and Mills (*loc. cit.*) methyl-arabinoside, β-naphthylarabinoside, *o*-cresyl-arabinoside, and carvacryl-arabinoside.—Report on the metamorphosed sedimentary and igneous rocks of the Ox Mountain range in Mayo and Sligo, and of their being probably a continuation of the similar rocks to the west in Mayo and Galway, also that they most likely extend northwards into Donegal and Londonderry, by Mr. A. **McHenry.** Opinions were stated as to the probability that the igneous rocks were contemporaneous in age with the granitic and associated basic rocks of Leinster; that is, that they belong probably to early Devonian time. Also that the sediments into which the igneous rocks of the west and north-west intrude are mainly of Ordovician age, with occasionally Upper Silurian sediments included, as in the case of the Wenlock quartzite of Croagh Patrick Mountain, south of Clew Bay.—On the antipodal relations of the eruptions and earthquakes reported as having occurred since January, 1901, by Prof. J. P. **O'Reilly.** The paper details the principal earthquakes and eruptions mentioned as having taken place since the commencement of 1901, giving the essential particulars regarding the points cited, as also the antipodal relations in each case. It is stated that of the centres of eruption mentioned, between 91 and 92 per cent. lie in the northern hemisphere, giving rise, therefore, to antipodes situated in the southern hemisphere, and for the most part in the Pacific and South Pacific, in the neighbourhood of New Zealand, in the Indian Ocean and the island groups of these oceans, that is to say, in parts of the earth's surface usually considered as being in a state of continued immersion, and so far implying a certain connection between the seats of activity on land and their antipodals in these oceans.—To obtain the cubic curve having three given conics as polar conics, by Dr. J. P. **Johnston.** It was shown that the conditions that the three conics could be transformed by a linear substitution, so as to be the first deriveds of a ternary cubic, gave eight independent linear equations to determine the nine constants of the transformation. A method was then given by which the equation of the cubic could be at once written down in a short symmetrical form. The constants of transformation were seen to be the coordinates of the points of which the conics were the polar conics.—A report on the Irish Hepaticæ, by Mr. D. **McArdle,** forms a *résumé* of all papers on the subject since 1876. 170 species and 63 varieties are enumerated. The arrangement is the same as that adopted in the "Cybele Hibernica," of which it is intended to form part ii. A table of districts shows at a glance the rarity or frequency of each plant.

PARIS.

Academy of Sciences, July 6.—M. Mascart in the chair.—The secretary announced to the Academy the death of Prof. J. W. Gibbs, correspondant for the section of mechanics. (An obituary notice appeared in NATURE of May 7, p. 11.)—Study of the flow of sheets of water, by M. J. **Boussinesq.**—On new syntheses effected by means of molecules containing the methylene group associated with one or two negative radicles. The action of epichlorhydrin upon the sodium derivatives of acetone-dicarboxylic esters, by MM. A. **Haller** and F. **March.** The lactone obtained as the result of this reaction has been esterified with alcohol and hydrochloric acid. The ester was not isolated, since it suffers internal condensation, giving rise to a hydrofurfurane derivative, the properties and reactions of which are described.—The action of human serum upon the Trypanosomes of nagana, caderas, and surra, by M. A. **Laveran.** Human serum, injected into animals suffering from nagana, surra, or caderas, causes the temporary disappearance of the parasites from the blood of the animal. No other method of treatment has been found which causes even a temporary cure of these diseases. No other species of animal furnishes a serum having properties analogous in this respect to human serum, with the exception of a slight effect noticed in the serum from the ape.—Remarks on the formation of pollen in the Asclepiadeæ, by M. L. **Guignard.**—On a rapid method of obtaining a plan of a country by means of photographs taken from a balloon, by M. **Laussedat.** Maps taken photographically from balloons have hitherto required a laborious graphical treatment to reduce them to a plane; a purely optical method of treatment is now described.—Experiments on the resistance of the air, by M. G. **Eiffel.** A heavy mass, 120 kilogrammes, and carrying plates which could be varied in shape and size, as well as means of recording the velocity and air pressure, was allowed to fall freely. The formula usually given for the pressure is KSV^2, where S is the surface, V the velocity, and K a constant 0·125kg. As a result of these experiments, it was found that K increased with the surface, and with equal surfaces, increases with the perimeter p, such that $K=0{\cdot}032+0{\cdot}022\,p$.—Secular variations of secondary importance, by M. Jean **Mascart.**—On the lines of curvature of certain surfaces, by M. E. **Blutel.**—On the groups of Mathieu, by M. **de Séguier.**—On the fundamental functions of Poincaré and the method of Neumann for a frontier composed of curvilinear polygons, by M. S. **Zaremba.**—On the characteristics of the vowels, the vocal scales, and their intervals, by M. l'abbé **Rousselot.**—On a species of oscillation of the chromatic perception, by M. C. **Maltézos.**—Consequences of the theory of nickel steels, by M. C.-E. **Guillaume.** The theory that the anomalous behaviour of nickel steels is due to the transformation of iron from the α to the γ state, and inversely, is applied to the explanation of experiments by Howe, Nagaoka and Honda, and Curie with satisfactory results.—On the diminution of the potential for any spontaneous change in a medium at constant temperature and pressure, by M. **Ariès.**—The action of iodine on thin pellicles of copper, by M. **Houllevigue.** It was found as a result of these experiments, that the smallest molecule of copper capable of reacting chemically with the vapour of iodine is of dimensions of the order of 40 μμ. Its weight is of the order of 5×10^{-18} milligrams.—Simplification of the analysis of silicates by the use of formic acid, by M. A. **Leclère.** After opening up the silicate by fusion with an appropriate base, the use of formic acid in the place of nitric acid is recommended in the subsequent separation of the silica and titanium.—On the conditions of production and stability of thiosulphuric acid, by M. J. **Aloy.** Thiosulphuric acid can be produced by the action of an alcoholic solution of sulphur dioxide on sulphur; the presence of alcohol and of neutral salts increases the stability of the acid.—On the esterification of the hydracids, by M. A. **Villiers.**—On dibromo-acetylene, its purification, cryoscopy, and analysis, by M. P. **Lemoult.** By the action of alcoholic potash upon tribromoethylene, and fractionation in the complete absence of oxygen, pure dibromo-acetylene can be obtained. The formula CBr:CBr was established by analysis and cryoscopic determinations in acetic acid solution.—On lactase, by MM. Em. **Bourquelot** and H. **Hérissey.** Lactase and emulsin are probably two distinct ferments, since emulsin without lactase can be obtained from *Aspergillus niger* and *Polyporus sulphureus*, lactase without emulsin from kephir, and the two together in several species of almond.—The action of sodium on carbon tetrachloride and chlorobenzene: formation of triphenylmethane and hexaphenylethane, by M. Jules **Schmidlin.**—The preparation of primary alcohols by means of the corresponding acids, by MM. L. **Bouveault** and G. **Blanc.** The method of reduction previously described, sodium in boiling alcohol, has been extended to other fatty acids. Aromatic acids with the carboxyl group in the ring resist the reduction.—The internal ethylene oxide of β-cyclohexanediol-1.2, and its derivatives, by M. Léon **Brunel.**—On the amount of acids soluble in ether in wines, considered as a means of differentiation, by M. Ch. **Blarez.**—The heat of neutralisation of hydroferrocyanic acid; the heat of formation of its compounds with ether and acetone, by MM. **Chrétien** and **Guinchant.**—On the fatty acids of egg lecithine, by M. H. **Cousin.** It is shown that egg lecithine contains, besides the derivatives of stearic, oleic, and palmitic acids already known, a derivative of linoleic acid.—The intravenous injection of glycerol; the estimation of the glycerol in the blood and its elimination by the urine, by M. Maurice **Nicloux.** Glycerol disappears very rapidly when injected into the blood, and appears in the urine in notable quantity very soon after injection.—The carbohydrates of barley and their transformation in the course

of germination as carried out on the industrial scale, by M. L. **Lindet.**—Researches on the constitution and structure of the cardiac fibres in the lower vertebrates, by M. F. **Marceau.**—On the suprarenal capsule in amphibia, by M. Ed. **Grynfeltt.**—Experimental pathogenetic segmentation in the eggs of *Petromyzon Planeri*, by M. E. **Bataillon.**—The meriphyte in the Cycadaceæ, by M. H. **Matte.**—On two Cephalopod layers of the Upper Devonian in the Sahara, by M. Émile **Haug.** These fossil-bearing layers present remarkable palæontological affinities with the layers of the same age in central Germany.—On the variations of the Meuse at the quaternary epoch, by M. Paul **Bois.**—On the retrogradation of starch, by M. L. **Maquenne.**—On an oxidising bacterium, its action on alcohol and glycerol, by M. R. **Sazerac.** There exists in certain wine vinegars an oxidising bacterium which differs both in its appearance and cultures from the sorbose bacterium, and which is capable of rapidly oxidising glycerol to dioxyacetone. Its acetifying power is very small.—On the production of glucose under the influence of asphyxia by the tissues of *Bombyx mori*, at various phases of its evolution, by M. F. **Maignon.**—On the production of hydrogen sulphide by extracts of organs and albumenoid materials in general, by MM. J. E. **Abelous** and H. **Ribaut.**—Study of the marine circulation, by M. J. **Thoulet.**

New South Wales.

Royal Society, May 6.—Prof. Warren, president, in the chair.—The president delivered an address on the development and progress of engineering during the last twenty-one years. In the course of his address he remarked that the wonderful progress during that time, and the great activity to-day in all branches of science and engineering, suggests great possibilities in the future. All future progress in engineering must depend upon exact knowledge and scientific thought and work. Our systems of primary, secondary, technical, and professional education must be carefully reconsidered in order to bring them up to the needs and requirements of modern civilisation. The engineer of the future must be a still more widely trained and better educated man than his predecessor of to-day, so that he may be better able to solve the many problems which lie before him in the future.

Linnean Society, April 29.—Dr. T. Storie Dixson, president, in the chair.—Australian fungi, new or unrecorded. Decades iii.-iv., by Mr. D. **McAlpine.** Of the fungi here recorded, fifteen are described as new species, fourteen genera being represented. The orchids, which are generally comparatively free from fungi, contribute two, one of the genera (Amerosporium) being new to Australia.—Notes on Australian Rhopalocera: Lycænidæ. Part iii., by Mr. G. A. **Waterhouse.** This part deals fully with the descriptive portion of the subject and with the nomenclature.—The bacterial origin of the gums of the Arabin group, by Dr. R. Greig **Smith.**—On some new or unrecorded species of West Australian plants, by Mr. W. V. **Fitzgerald.** The following are described as new:—(1) Hensmania, gen. nov., founded upon *Xerotes turbinata*, Endl., of which perfect flowers were previously unknown, and of which Mr. Bentham did not see specimens in fruit. (2) Six species referable to the genera Leucopogon, Conostylis, Centrolepis, Restio, Hypolæna and Cyathochæte, and four to Schœnus. Two species, *Anisacantha (Bassia) longicuspis*, F.v.M., and *Stipa Tuckeri*, F.v.M., are now recorded from West Australia for the first time.—The vegetation of New England, N.S.W., by Fred. **Turner.** The New England district lies between 29° and 31° south lat., and 151° 20′ and 152° 20′ east long., and has an average elevation of about 3500 feet. Its flora may be described as intermediate in character between the subtropical and in places very dense and luxuriant vegetation of the coastal strip between its eastern boundary and the sea and that of the plains to the west, consisting of trees and shrubs of a more dwarf habit, and generally with less luxuriant foliage, except near water-courses. The census of the phanerogams and vascular cryptogams now brought forward yields a total of 369 genera and 708 species.

May 27.—Dr. T. Storie Dixson, president, in the chair.—Australian Psyllidæ, part iii., by Mr. W. W. **Froggatt.** Sixteen species are described as new, including three fine gall-making species of Trioza—two from Tasmania, and the third from Queensland, which is remarkable for its curious, open, saucer-like galls, in form approaching those of some of the gall-making Coccids.—On a revision of the Eucalypts of the Rylstone District, N.S.W., by Mr. R. T. **Baker.** In a previous paper twenty-two species of Eucalypts were enumerated. As the result of further collecting and study in the interval, the number of species now recognised has been increased by ten, while some of the earlier determinations have been reconsidered and amended.—A slime bacterium from the peach, almond and cedar (*Bact. persicae*, n.sp.), by Dr. R. Greig **Smith.** The organism produces a slime, the essential carbohydrate of which readily becomes converted to an insoluble modification. The carbohydrate is easily hydrolysed to arabinose and galactose, the latter sugar preponderating. The insolubility of the gummy constituent when heated under pressure shows that it does not belong to the arabin group. The soluble gum is coagulated by the acetates of lead, barium hydrate, milk of lime, and aluminium hydrate. The insoluble modification is easily dissolved by dilute acids, but not by dilute alkali. A small quantity of gum behaving to reagents like the bacterial gum was separated from the natural gum of the almond.

EXPERIMENTAL MORPHOLOGY.

Willkürliche Entwickelungsänderungen bei Pflanzen. Ein Beitrag zur Physiologie der Entwickelung. By Georg Klebs. Pp. iv + 166. (Jena: G. Fischer, 1903.) Price 4 marks.

THIS is practically a continuation of Dr. Klebs's well-known work "Die Bedingungen der Fortpflanzung bei einigen Algen und Pilzen" (Jena, 1896), but whereas that was concerned with the lower organisms the present work deals with phanerogams. Both works are contributions to experimental morphology, the essential feature in both being the performance of a series of experiments skilfully planned so as to discover the nature of the external conditions which lead to certain definite changes of form or function in plants. Englishmen will be glad to see that to Andrew Knight is given the honour of being the founder of this type of work; then follow Hofmeister, Vöchting, Sachs, Goebel, Bonnier, &c., nor should it be forgotten that Klebs himself has worked steadily and with brilliant effect on this line since 1889.

Klebs's aim is definitely objective; he seeks to discover facts, without regard to whether the changes arising under given conditions are adaptive. He nevertheless allows himself to postulate a certain mechanism in the organism by which he conceives it possible that external conditions produce their effect. His discussion is interesting, but his terminology seems to us open to criticism, nor does his theory strike us as essential to his aim—the foundation of causal morphology in a purely objective sense. He takes, as an instance, the undifferentiated cells in the growing-point of a plant, in which reside the possibility of developing into organs characteristic of the species. The physical substratum in which this potentiality resides he calls "specific structure." This he assumes to be constant, which implies (we imagine) that under certain definite conditions it always develops an identical form, while if the conditions are different the form will be different. Under the heading "conditions" he distinguishes external and internal. He retains the term external as being already in common use, though he seems to prefer the expression "directe oder unmittelbare äussere Bedingungen." These are the various chemic, thermic, photic, and mechanical influences which act on the organism from its earliest stages. The definition of the inner conditions is as follows:—

> "Every phenomenon of life occurs within the organism; it is a consequence of the internal conditions ruling at the moment. The quality and quantity of the substances present in the cell, the various kinds of ferments, the physical properties of the protoplasm, cell-sap, cell-wall, &c., all these belong to the internal conditions,"

and are "in the first instance supplied to the individual by its origin from a previous generation."

He also strongly insists on the internal conditions being completely distinct from the specific structure. We fail to see that a real distinction between internal and external conditions is made good. For instance, a naked protoplast placed in a nutrient fluid—a solution of glycerin—is subjected to new external conditions. But a vegetable cell treated in the same way takes up glycerin into its cell-sap, and by the above definition the physical properties of the cell-sap are internal conditions. Yet in both cases the change consists in exposing protoplasm to a certain solution. Nor again can we clearly distinguish between internal conditions and specific potentiality. In a mechanical theory such as Klebs's the "specific structure" must depend on the physical properties of protoplasm, yet these last named are said to be part of the internal conditions.

All that Klebs proves by his experiments is that a change of external conditions determines a change in the form and physiological processes of the organism. We may conclude from this that the undeveloped tissues are under the rule of changing conditions, but have we a right to draw any other conclusion? Klebs has shown that Saprolegnia grows continuously if supplied with good culture-fluid, but that it at once forms zoosporangia if the culture-fluid is replaced by pure water. The same thing happens if the fungus is left to itself with a limited supply of food, *i.e.* it forms zoosporangia when the nutriment runs short, thus by its own activity it makes the conditions necessary for zoospore formation. Or, what is another way of putting the matter, the artificial exchange of nutrient fluid for pure water induces zoosporangium-formation because it is an imitation of the natural series of changes to which the plant is subject. Klebs does not pretend to say how pure water leads to zoosporangia being formed; he shows it to be a necessary condition, but the causal connection is absolutely unknown. It possibly always will be so, but it is at least possible to give the problem its proper place among cognate questions, *i.e.* those relating to reflexes. These are most conveniently studied in the facts of movement, but there is no reason for excluding the facts of experimental morphology. In our opinion, the purely objective method applied to reflexes is incomplete; we differ markedly from Klebs in thinking it impossible to deal fully with the question without taking adaptiveness into account. The fact that a stem bends upwards when deflected from the vertical, depends on some strain or pressure produced in the protoplasm by such deflection. We call this a stimulus, but only because it precedes the act of curving and by endless repetition is associated with that act. What was originally a physical concomitant of a certain position of the plant in relation to the vertical comes to be a stimulus. It may be said that the primeval plant which acquired geotropism did so because there is some unknown but necessary connection between mechanical strain applied to protoplasm and the act of curving upwards. But if so why are essentially similar plants stimulated to downward curvature by a like strain? Only a vague answer can be made from the objective point of view. From the adaptive point of view there is no difficulty; any curvature may become associated with any physical change in the protoplasm, upon which it normally and continuously follows. The importance of natural selection is here obvious, for it picks out the

plants which have the capacity of association, and which, to speak metaphorically, are able to use changed conditions as signals for serviceable movements. Without selection we cannot conceive the forging of the chain of inherited habit which binds plants to the performance of adaptive movements.

It is true that we cannot say in what the association consists, and it will doubtless be said that our point of view only differs from that of Klebs in substituting "stimulus" for "conditions." The difference is essential, for we take into account natural selection as a universal condition under which all organisms subsist.

We must be content to differ from Dr. Klebs, who goes so far as to say (p. 162) that the adaptation (Zweckmässigkeit) of organisms is in no way (gar nicht) a scientific problem. We are none the less ready to welcome his researches, of which we proceed to give some account.

Among the results obtained by Klebs some of the most interesting are the experiments in which, by appropriate culture conditions, he converts an inflorescence into an ordinary vegetative shoot. For instance, by making a cutting of the flowering shoot of *Veronica chamaedrys* and growing the plants in damp air, he converts an organ of limited growth into one of unlimited growth, with leaves differing in size, character of hair and phyllotaxy from those of the inflorescence, and resembling the ordinary vegetative shoot.

Another interesting series of observations is on *Glechoma hederacea*, which, if grown in a greenhouse and watered with nutritive solution, never flowers, whereas parts of the same individual plant, grown in small pots in summer and kept cool in winter, flower in the following summer. By special treatment he even compelled flowers to appear on the runners, whereas normally only the upright shoots bear flowers. *Ajuga reptans* bears runners in the axils of its rosette-leaves; these form in the autumn new terminal rosettes, the central shoots of which flower in the following spring. This is the normal state of things, but Klebs converted a flowering shoot into a runner by darkness and damp heat, and also produced other curious anomalies of development. In another experiment on the same type he introduced a runner into the lower end of a cylinder of water, when its normally horizontal growth was changed and it grew straight up until it reached the air, where it once more became horizontal. Klebs devotes a section of his book to a discussion of the facts of regeneration for which we are largely indebted to Vöchting. Klebs points out that we do not even know why the severance of a part from its parent should lead to a regenerative outgrowth of roots and shoots; he goes on to demonstrate by experiments that in *Salix vitellina* a branch, without being severed from its parent, can be forced to make roots by submergence in water. He uses this fact as an argument against the adaptive explanation of the behaviour of cuttings. It proves, of course, that some of the phenomena are producible without severance, but the facts of severance remain; two different stimuli may produce the same result, as in the well-known experiment of Pfeffer in which the root-hairs of the gemmæ of Marchantia develop on the physically lower side and also on the side in contact with a solid body.

Another section of the book deals with the length of life of plants and the cognate facts on resting periods in vegetable growth. He shows that Parietaria can be kept in constant flower for two years. That in annuals there is no inherent limit to their development, as he proved by making a series of cuttings of the growing shoots. Again, he compelled the winter buds of Gratiola to germinate (contrary to their habit) without a resting period, by cultivating the plant under water and placing it in a greenhouse in autumn. These may serve as examples of the experimental work in which Dr. Klebs is engaged. It is evidently a research which tests to the full his ingenuity and determination, and it is one in which all naturalists will wish him the success he deserves.

The book concludes with a section on "Variation and Mutation," which will be useful to old-fashioned evolutionists in showing the trend of certain younger schools of thought.

FRANCIS DARWIN.

NITROGEN AND ITS COMPOUNDS.

Der Stickstoff und seine wichtigsten Verbindungen. By Dr. Leopold Spiegel. Pp. xii+912. (Braunschweig: Vieweg und Sohn, 1903.) Price 20 marks.

THE large and ever-increasing amount of work turned out by research chemists in all branches and departments of the science, and the dispersal of the results of investigations throughout a sufficiently extended array of publishing media, awaken the demand for some means by which the wealth of newly-acquired knowledge may be made easily accessible; and the editor or author who undertakes the very tedious but important task of collecting from the different sources and arranging in a summarised form all, or even the most important, facts which have been established, performs a service to his science for which he does not always receive due credit.

The importance of the compounds of nitrogen for the study of valency and the formation of complex compounds, the important position which they occupy in investigations into the laws of stereochemistry, and, in the case of the carbon compounds, the determining influence of the nitrogen atom on the character of the molecule, have led the author to the compilation of a volume which brings together all the most important known facts with regard to the chemical and physicochemical relationships of this element and its compounds. No separation is made of the organic from the inorganic compounds, but the latter are treated much more fully than the former. With regard to the organic compounds of nitrogen, the author has wisely refrained from a duplication of "Beilstein," and has contented himself with pointing out the more important characteristics, and with giving in tabular form the chief representatives of the different groups.

The whole matter is arranged under the following headings:—the element, halogen compounds of nitrogen, oxygen compounds of nitrogen, sulphur compounds of nitrogen, hydrogen compounds of

nitrogen, metal nitrides, phosphorus compounds of nitrogen, arsenic nitride, carbon compounds of nitrogen, silicon nitride, titanium compounds of nitrogen, zirconium nitride, boron compounds of nitrogen, nitrogen in closed rings, alkaloids, protein substances, analytical methods, addenda.

The treatment of the element and its important inorganic compounds, *e.g.* nitric acid and ammonia, seems very satisfactory, although, for instance, the action of hypobromite on ammonium chloride might well have been included in the list of methods of preparing nitrogen, instead of merely being referred to incidentally in another connection.

Apparently no attempt has been made to sift critically the large accumulation of material at the author's disposal, and the book therefore assumes the character of a dictionary. Nevertheless, several cases are to be found where a more connected treatment is given to the subject, as, *e.g.* in the description of the steps by which the formation of nitric acid in the soil was traced to a specific ferment, or in the account of the application of Werner's theories to the constitution of the metal ammonia compounds. Such accounts, although written in briefest outline, serve to direct attention to points of importance in theoretical chemistry. The account of the diazo-compounds one could wish fuller, and some reference might have been expected to Goldschmidt's important work on the dynamics of the diazo- and azo-compounds. In mentioning the transformation of ammonium thiocyanate (the melting point of which is 149°, not 159°) into thio-urea, also, the work of Waddell might have been referred to. Further, in the analytical portion of the book, although various methods are given for the estimation of nitrogen in organic compounds, no mention is made of the Frankland-Armstrong modification of Dumas's method, although it is probably the most convenient and accurate method of estimation.

In compiling the book, the chemical literature up to 1900 has been taken into account; and in an appendix additions and corrections are given bringing the work up to 1902. In spite of some omissions, the book will be readily welcomed as an important addition to the works of reference in chemistry, and the author deserves the thanks of his fellow-workers for the trouble he has taken in the compilation. A. F.

PROSPECTING.

La Prospection des Mines et leur Mise en valeur. By Maurice Lecomte-Denis. Pp. xv+551, with 320 figures. (Paris: Schleicher, 1903.)

WHEN an author is fortunate enough to have such a godfather for his book as M. Haton de la Goupillière, it may be taken for granted that the work contains much useful matter. The book is intended not so much for the old-time prospector, armed with pick, shovel, and pan, who wanders about in search of gold, as for the scientific mining engineer called upon to report upon a mineral deposit already discovered, and possibly already worked on a small scale. M. Lecomte-Denis tells the novice how to set about his work, and how to draw up his report to his employers, and he points out useful precautions to be observed in purchasing mines and minerals. The motto for the chapter upon "salting," "*Défiance est mère de sûreté,*" is well chosen; many of the common tricks of fraudulent mine-vendors are exposed by the author, who most wisely advises the inspecting engineer to err on the side of scepticism when making his examinations.

Next come two purely geological chapters upon the distinctive characters of the igneous and of the sedimentary rocks. It is doubtful whether it is wise to burden a book upon prospecting with more than three hundred figures of fossils. M. Lecomte-Denis points out, however, that the traveller cannot carry a geological library with him, and that it will probably be a convenience to him to possess a little palæontological information for immediate reference on the spot.

Six chapters are devoted to the study of the modes of occurrence of the most important useful minerals, viz., coal, petroleum, bitumen, and the ores of iron, copper, zinc, and lead. Many useful commercial data are appended. Similar information concerning phosphates, bauxite, and the ores of tin, mercury, &c., is promised in a later edition.

When a mineral deposit has been found, it is usually necessary to investigate its commercial value by certain preliminary workings. The manner of carrying these out and of making deductions from the results obtained is treated in a long and useful chapter. The author speaks wisely with regard to writing reports when he bids the engineer weigh his words very carefully, for extracts may be made, and words may be twisted, so as to convey a meaning very different from that which was intended. The greatest prudence is necessary on the part of inspecting engineers with the object of not raising his employer's hopes too high, nor, on the other hand, by an unnecessarily pessimistic tone, of preventing him from embarking upon an undertaking which may have many chances of success. What is required is complete frankness; let the capitalist know the grounds upon which the engineer bases his opinions. If the former is in doubt, he can then go to a consulting mining engineer and say, "Supposing these data to be true, what is your advice?"

The inspecting engineer should certainly make himself acquainted with the mining laws of the country in which the property upon which he is reporting is situated; and the brief remarks of M. Lecomte-Denis upon foreign mining jurisprudence may serve as a first step in the study. On the other hand, more space is devoted to an exposition of the mining laws of France than seems to be necessary.

The tables at the end of the book are similar to those found in the usual miners' pocket-books. Some palpable errors show that sufficient care was not taken in preparing them for the press, and consequently the reader may feel a little sceptical about their trustworthiness. On the whole the book is likely to prove useful to the mining engineer, for it deals with matters which are usually considered somewhat outside the scope of the ordinary text-books.

OUR BOOK SHELF.

The Revival of Phrenology. The Mental Functions of the Brain. By Bernard Hollander, M.D., &c. Pp. xviii + 512; illustrated. (London: Grant Richards. 1901.) Price 21*s*. net.

According to Dr. Hollander, the connection between mind and brain has long been waiting for a discoverer, and he is determined that it shall wait no longer. "The present work aims at clearing up the mystery of the fundamental psychical functions and their localisation in the brain. It is the first work on the subject since the dawn of modern scientific research." We expect that an author who claims to clear up a mystery and to write the first work on a subject since the dawn of scientific research should at least be acquainted with the present position of the science with which he deals, but we do not find that Dr. Hollander has satisfied this preliminary requirement. The very title of his book indicates that he is not before, but behind the age. Mental phenomena are not functions of the brain in the modern medical meaning of the term "function," and if by "the fundamental psychical functions" Dr. Hollander means the primary divisions of mind as recognised in modern psychology, then we cannot find evidence in his book that he knows what they are. "Most men," he says, "regard mind as though the term were equivalent to intellect and did not include the feelings and fundamental impulses." "The great majority hold mind to be equivalent to intellect." We do not know whether by "most men" and "the great majority" Dr. Hollander means the majority of the whole population, or of the whole male population, or of neurologists, or of psychologists. If he means either of the two former, he is probably wrong. If he means either of the two latter, he is certainly wrong; so wrong that it is difficult to believe that he has opened a book on psychology that has been published within the last half-century. When a writer presumes to lecture the whole world of psychologists in the tone of the Supreme Being addressing a group of blackbeetles, he should at least make himself acquainted with the rudiments of their terminology. He would then avoid speaking of "faculties" as "forces." He would not say that "satisfaction, discontent, desire, fear, anger . . . &c., are so many states of our internal organisation which . . . exist . . . without consciousness . . . being necessary."

"The data amassed by the author," Dr. Hollander modestly asserts, "are so considerable as to open up quite a new field for research." These data consist of more than 800 cases, which are alleged to illustrate the connection between some special brain-area and some special phase of mind. The first group are "cases of melancholia due to injury to the central parietal area." A number of cases of injury to the parietal region are adduced, but in many of them there is little or no evidence of melancholia. Whenever, in the reports, the word depression is used, Dr. Hollander accepts it as the equivalent of melancholia, though it is quite obvious that in many cases it means hebetude, stupor or coma. Melancholia is attributed to blows on the parietal region that were inflicted four years, five years, six years, fourteen years, seventeen years before the patient came under treatment. Of the innumerable multitudes of cases of lesion of the parietal region without any sign of melancholia resulting, not a word is said. This is not scientific investigation; it is special pleading. Dr. Hollander pleads that in view of the important bearing of his facts upon the entire development of medical science, on the study and treatment of lunacy, on the education of the young, &c., the evidence and statements may be received willingly and in fair spirit, however critical. We have endeavoured to comply with his request. We have weighed his evidence, and it seems to be of the same value as his statements.

St. Kilda and its Birds. By J. Wiglesworth. Pp. 69; illustrated. (Liverpool: C. Tinling and Co., 1903.)

On his return from an ornithological trip to the St. Kilda group last summer, Dr. Wiglesworth delivered before the Liverpool Biological Society a lecture on these islands and their inhabitants—human and otherwise. This lecture has been published in the volume before us, and although the author has little or nothing absolutely new to tell, he has undoubtedly succeeded in producing a very interesting work, which ought to be invaluable to all future tourists in these islands. Although the extension of the breeding range of the fulmar-petrel to the Shetlands has deprived St. Kilda of one of its claims to preeminence, yet it possesses an absolutely peculiar form of wren as well as two mice of its own, while it is also one of the chief breeding-places of the fork-tailed petrel. Moreover, its breeding-list of other sea-birds is comparatively large, so that the island possesses especial interest for the ornithologist and egg-collector. Unfortunately, the latter individual has of late years made himself somewhat too conspicuous, and "when it comes to dealers giving unlimited orders for fork-tailed petrels' eggs at prices which set the whole male population of the island on the alert to dig out every petrel-burrow they can possibly come across, one cannot but feel considerable anxiety as to the future of this interesting species." High prices are likewise paid for the eggs of the St. Kilda wren, of which large numbers are exported. It would therefore seem that the island stands in urgent need of the special attention of those interested in bird preservation. One of the features of St. Kilda is the number of species of petrels by which it is inhabited, while not less noteworthy are the hordes of puffins which swarm over its grassy slopes, and tenant almost every available nook amongst the rocks and boulders.

But it is not only for its birds and mice that the St. Kilda group has a special claim on the interest of the naturalist. One of the islets, Soa, or Soay, is remarkable as being the only locality in Great Britain where sheep exist in a wild condition. It appears that in the latter part of the eighteenth century the owner of St. Kilda laid claim to one out of every seven sheep born in the main island. These sheep were carried to Soa, where, in the absence of anyone to look after them, they ran completely wild. And by this accident has been preserved to our own time the very small and peculiar breed of sheep which was probably once common to St. Kilda and most of the western islands, but has everywhere, except in Soa, been modified by the introduction of other breeds. Most of these sheep are light brown in colour, although a few are almost black, and others nearly white. They are so wild and shy that they cannot be approached within 100 yards, except by careful stalking, while their activity and speed are such that they cannot be hunted down by the dogs of the islanders. A ewe of this sheep, as well as the skull of a ram, are exhibited in the Natural History Museum. R. L.

The Principal Species of Wood. By C. H. Snow, C.E., Sc.D. Pp. xi + 203. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 15*s*. net.

In producing this work the author has evidently spared himself no pains to collect a vast amount of statistics concerning the genera and species with which he deals. The work is also profusely illustrated by plates, and these, along with the general equipment of the book, reflect credit on artist and publishers. Tabulated statements concerning the different species are given, and contain data such as modulus of elasticity and rupture of wood, as well as notes on its various struc-

tural qualities and representative uses. These will prove of value to both expert and amateur.

From its title one might be led to suppose that the book was an addition to the literature of strict forest botany, but the preface states that "It is intended for those who are not foresters or botanists, but who use woods or desire a knowledge of their distinguishing properties." The preface further states that "Although great care has been taken to check each fact, errors no doubt exist, although it is not believed that there are important ones." We cannot entirely agree with the author in this. For example, in the introduction we are told that a true wood fibre originates from several cells, "a resin duct is a cell structure or a fibre," "a vessel is a short wide tube joined vertically end to end with others of its kind."

Inaccuracy and vagueness of expression are to be found elsewhere in the book. For instance, "Europeans regard the Ash for ornamental purposes, but Americans value it for wood" is an error that may perhaps be excused in an American writer, but why should the leaves of Eucalyptus be described thus?—"Those of young blue gums are bright blue, oval and stalkless, while leaves of older trees have stems (*sic*), are dark green and sickle-shaped."

Attention is further directed in the preface to the fact that "Allusions to trees, historical and other references, aside from those directly regarding woods, are made for completeness and in order to mark, distinguish, or separate the species." The author fails to realise this object. The distinguishing characters given are far too vague and general to be of any practical value.

On the whole the book contains much useful information and statistics regarding the various species of wood, both broad-leaved and coniferous. It would have been much better, however, had the author confined himself to the treatment of this aspect of the subject alone, leaving out all botanical and other technical matter.

Lehrbuch der Mikrophotographie. By Dr. Carl Kaiserling. Pp. viii + 179. (Berlin: Gustav Schmidt, n.d.) Price 4 marks.

ALTHOUGH there are several well-known treatises on this subject, it is doubtful whether any exceed in thoroughness the one now under notice. The essential conditions for the production of photomicrographs of the highest class are carefully described, and each part of the process is treated fully.

There is no more important point than the illumination of the object itself, and both the source of light and its colour should be selected to bring out the desired points in the resulting photographs.

This part of the subject is generally treated all too briefly, but in the present instance its importance is evidently recognised. The various ways of making light filters and their use with coloured preparations are described. The method of arriving at the proper filter to use with a given preparation is stated to be by determining the absorption spectrum of the dye used for staining, by aid of a hand spectroscope, and then adapting the light filter to give the result desired. This is undoubtedly the only scientific method of using colour screens in photomicrography, and one which we have adopted with success for some time past.

The various types of apparatus by the leading makers are fully described, prominence being naturally given to continental firms. Instructions as to the use of substage apparatus, methods of centring, choice of objectives, and the combination of microscope and camera are included, while it is satisfactory to note that no space is unnecessarily wasted over purely photographic processes. Altogether the book may be recommended to photomicrographers as one of the best yet published. J. E. B.

LETTERS TO THE EDITOR.

The Source of Radium Energy.

THE novel and unforeseen property of radium of producing energy, which purely kinetic theories, in opposition to the notion of inherent force as a transcendental element, do not seem able to explain, is perhaps destined to give a fresh impetus to discussion from the two distinct points of view. It is meanwhile to be noted with regard to this, that the notion of force acting at a distance from point to point, being equal and reciprocal between the various material points, does not appear to be any better met by the manifestation of the unfailing energy of radium than the simple movements of the kinetic theory. This remark justifies attention being directed to a view of the natural physical forces presented by the present writer more than ten years ago (see Lagrange's "Study of the System of Physical Forces," forming vol. xlviii. of the *Memoirs* of the Royal Academy of Sciences of Belgium). It is there shown that forces exist of such a nature that static equilibrium is impossible, on the impact of bodies of different composition, at their surfaces of contact. They are forces making a body, after the example of radium, emit rays unceasingly without apparent loss of substance. A force of repulsion is referred to here, emanating from the surface, and not from the centre of the mass of atoms, acting on opposed surfaces, and the varying intensity of which is nothing else than what is known to science as absolute temperature. That repulsive force, acting in the inverse ratio of the volume of matter (or of the cube of the distance), just as Newtonian gravitation acts in the inverse ratio of the surface (or as the square of the distance), takes its immediate development, and to some extent visible shape, in Mariotte's law of the relation of pressure to volume in gases. The memoir establishes the existence of a continuous interatomic medium of transcendental qualities not yet understood, conveying the effect of a force acting at the surface of atoms, and the real seat of luminous and electromagnetic wave motion, according to the views to which clearly Lord Kelvin has of late returned. The view now presented is entirely deduced from analysis of the actual facts, worked out at length, and justified by the memoir, and new so far as the case of the impossibility of an equilibrium due to the surface force of repulsion, which gives rise to an exhaustless emission of energy. The reflecting attention of physicists may therefore be legitimately directed to the subject, because it seems certain that the new properties which radium manifests are not explainable by the kinetic hypothesis, but, on the contrary, are of a nature henceforward to modify considerably the speculations of modern physics.

Brussels, July 14. CH. LAGRANGE.

A New Case of Phosphorescence induced by Radium Bromide.

IT is known that salt (NaCl) at a temperature of 200° C. is phosphorescent (*vide* Phipson on "Phosphorescence," p. 20); during a course of experiments in June last I found that radium bromide induces phosphorescence at ordinary temperatures. The following is a convenient way of observing the phenomenon. Fill a wooden match-box with table salt removed from the inner portion of a block; press the radium bromide tube into the yielding mass and just barely cover it with the substance. If it be now put on one side for a few hours, say into one of the compartments of a chest of drawers, on opening the box in the dark all round the tube will be found to phosphoresce with a white light, but, unlike zinc blende and barium platinocyanide, the salt continues visibly to phosphoresce after removal of the radium bromide. The portions of salt round the tube are turned of a faint buff or ochrey tint. The image of the visible portion round and where the radium bromide tube has lain is impressed on a photographic plate in thirty

minutes, but only very faintly in two or three minutes. I have tried samples of salt from several localities with the same results.

WILLIAM ACKROYD.

Tables of Four-figure Logarithms.

I AM much interested by the short letter, contributed by Prof. Perry to NATURE of July 2 (p. 199), on the subject of four-figure logarithms, especially as I have myself offered a solution of the difficulty which Mr. Harrison has essayed to remedy. If, instead of using Bottomley's differences for the upper part of the tables, viz. from 1000 to 1799, we resort to the usual tabular differences found in any ordinary logarithmic tables, such as Chambers's, we get an even greater accuracy than does Mr. Harrison. The tables are naturally weakest when we have a "9" for the fourth figure of the number the logarithm of which is required. Taking this as a test, between 1000 and 1799 the accuracy of the three methods may be expressed thus:—

	Per cent.
Bottomley's differences	37·5
Ditto, Harrison's extension	58·5
Ordinary tabular differences	76

Tabular differences would be required corresponding to logarithmic differences of 43 to 24 inclusive, *i.e.* twenty small columns of differences. It may be objected that it would be unwieldy in use to change from one method of procedure to another, but I think it will be found, also, that Mr. Harrison's tables are not so easy to use as the unmodified ones. The tabular differences might, indeed, be printed down the side of Bottomley's table without disturbing the usual differences, and only be used when the best possible accuracy is desired.

One of the best solutions of the difficulty has been suggested to me by Prof. Perry himself, viz. divide the number, less than 2000, the logarithm of which is wanted, by 2, and add together the logarithms of quotient and divisor. The approximation to the true logarithm of the number is very good.

I cannot agree that chemists, in any case, should use four-figure logarithms, seeing that they habitually return four figures as significant. I hope, before long, to be able to show that practicable five-figure tables can be constructed to which the reproach of "size" will be inapplicable.

July 3. M. WHITE STEVENS.

PROF. PERRY in NATURE of July 2 (p. 198) gives an illustration of a method whereby the logarithms of the numbers from 1000 to 2000 may be got from a four-place logarithm table with an error of, at most, one unit in the last place.

It is, however, somewhat difficult to see what advantage this arrangement has over the one where the logarithms of the numbers 1000 to 2000 are given (again) after 999 *in extenso* without proportional parts.

By this latter system the tables are certainly increased in size by another double page, but, on the other hand, there is a decided disadvantage in using the relatively large proportional parts for the numbers 1000 to 2000. If the addition of the proportional parts is done on paper, time will be lost; if the addition is done mentally, mistakes may easily occur.

C. E. F.

Edinburgh, July 4.

IN mathematical tables the last figure in any tabulated number or difference must be liable to an error $\pm\frac{1}{2}$. When a number is extracted from the tables by aid of a tabulated difference, the result is subject to a duplication of error, that is, to an error ± 1. It will be found on examination that in some of the early numbers of the ordinary four-figure log tables the error is often double this amount. Mr. Harrison's alteration remedies this mistake, and makes the maximum error uniform throughout. The scheme proposed by Mr. Stevens can do no more than this, and would be more clumsy. The figures given by him apparently refer to averages, and are irrelevant.

If the proposal of C.E.F. were adopted, the first portion of the table would have double the accuracy of the remainder; the result of any general calculation would depend on the accuracy of the latter, and little, if anything, would be gained in return for the fact that the space occupied by the tables would be doubled.

JOHN PERRY.

A Multiple Lightning Flash.

I HAVE had the privilege of examining the print of the lightning flash taken by Mr. C. H. Hawkins, of Croydon, and referred to in NATURE (July 16, p. 247) by Dr. W. N. Shaw.

The main flash consists really of *three* flashes, the several paths of which are not quite coincident. If a moving camera had been employed (I assume the camera in this case was fixed), then I think the three flashes would have been easily distinguished. The flash on the right is evidently a ramification of the main stream. Except for the above, the photograph shows no other special features.

WILLIAM J. S. LOCKYER.

Solar Physics Observatory, July 17.

The Lyrids, 1903.

THE return of the Lyrids this year was well observed here. Watching was begun on April 15, and continued until April 24, the series being broken only once, namely on April 20, when the sky was overcast. The weather was very favourable, the heavens on most nights being beautifully clear. Eighty-four meteors were registered, of which twenty were Lyrids.

The chief points with regard to the Lyrids brought out by the observations are:—

(1) The display was of moderate strength.

(2) The maximum occurred on April 21 and 22, probably more precisely at midnight on the latter date.

(3) The decrease in activity was more rapid than the rise to maximum.

(4) The radiant on the nights of April 21–22 was at $271\frac{1}{2}^\circ + 33^\circ$ (12 paths).

(5) The colours of the Lyrids were almost wholly of two shades, white and a peculiar yellowish, dirty-looking green.

(6) The meteors were swift, their average angular velocity being 20° a second, not taking into account those which appeared close to the radiant. The real speed of a Lyrid fireball recorded on April 22 by Prof. Herschel at Slough and the writer at Leicester has been computed to have been 39 miles per second.

(7) Only the very brightest Lyrids left streaks.

The first meteor of the shower was observed on April 17. There was a remarkable break on April 19, when not a single Lyrid was seen in a watch lasting three hours, though the seeing was excellent.

Minor Showers.

Besides the Lyrids, radiants were found for the chief active showers as under:—

Radiant-point	Duration	No. of meteors	Remarks
$330^\circ + 35^\circ$ ...	March 29–April 24 ...	4 ...	Slowish; radiant well-defined.
$216 - 26$ ...	April 11–24 ...	5 ...	Rather swift, bright, long. Exhibited great variety of colour.
$236\frac{1}{2} + 51\frac{1}{2}$ ...	April 19 ...	4 ...	Short; rather swift. Radiant sharply defined.
$256\frac{1}{2} + 37$ ...	April 19–22 ...	6 ...	Swift. Maximum April 22 (5 meteors).

The shower from 216°–26° is very interesting, inasmuch as nothing seems to have been seen of it previous to 1900, in which year it was very active at the Lyrid epoch from 218°–31°. It appears, therefore, to furnish quite a strong display at this period.

A recent writer has calculated that the maximum of the Lyrid shower would fall this year at April 19, 10h. 30m. My observations entirely negative this conclusion, for that night was marked by the complete absence of Lyrids, though the seeing conditions were extremely favourable. The time of maximum actually found was in accordance with that which had previously been inferred. Since in the last few years the maximum has taken place on the 20–21, it was to be expected that, after the omission of leap year in 1900, the epoch would be thrown one day later.

ALPHONSO KING.

Leicester, July 11.

THE WILD HORSE.[1]

IN the time of Pallas and Pennant, as in the days of Oppian and Pliny, it was commonly believed that true wild horses were to be met with, not only in Central Asia, but also in Europe and Africa. But ere the middle of the nineteenth century was reached, naturalists were beginning to question the existence of genuine wild horses; and somewhat later, the conclusion was arrived at that the horse had long "ceased to exist in a state of nature."[2]

This view had barely been accepted by zoologists when it was announced from St. Petersburg that a true wild horse had at last been discovered in Central Asia by the celebrated Russian traveller, Przewalsky.

An account of this horse was communicated by Poliakoff, in 1881, to the Imperial Russian Geographical Society.[3] The material at Poliakoff's disposal being limited, zoologists were not at once disposed to admit that Przewalsky's horse, as it came to be called, deserved to rank as a distinct species. Some believed the new horse had no more claim for a place amongst wild forms than the mustangs of the western prairies or the brumbies of the Australian bush; while others asserted it was merely a hybrid between the Kiang (*Equus hemionus*) and a Mongolian or other eastern pony.

Even after the brothers Grijimailo, in 1890,[4] added somewhat to Poliakoff's original description from material (four skins and a skeleton) brought from the Dzungaria desert, naturalists were still sceptical. The greatest English authority on the structure and classification of the Equidæ during the latter part of the nineteenth century was the late Sir William Flower. Writing in 1891, Flower says:—"Much interest, not yet thoroughly satisfied, has been excited among zoologists" by Poliakoff's announcement, but, he added, "Until more specimens are obtained, it is difficult to form a definite opinion as to the validity of the species, or to resist the suspicion that it may not be an accidental hybrid between the Kiang and the horse."[5]

Since Flower expressed this opinion, quite a number of specimens illustrating the form and structure of Przewalsky's horse at various ages have been added to the St. Petersburg Zoological Museum, and in 1902 Mr. Hagenbeck, of Hamburg (commissioned by His Grace the Duke of Bedford) imported from Mongolia between twenty and thirty living Przewalsky "colts." Though about half of these colts found their way to England, and though Dr. W. Salensky, director of the Zoological Museum of St. Petersburg, published last year an elaborate monograph[6] on Przewalsky's horse, English zoologists are not yet satisfied that we have in this member of the horse family a true and valid species.

So far as I can gather, it is generally believed in England that Przewalsky's horse is a hybrid—a cross between a pony and a Kiang. Beddard, however, admits it may be a distinct type. He says:—"This animal has been believed to be a mule between the wild ass and a feral horse; but if a distinct form—and probability seems to urge that view—it is interesting as breaking down the distinctions between horses and asses."[1]

It must be admitted that in its mane and tail Przewalsky's horse is strongly suggestive of a hybrid, but in the short mane and mule-like tail we may very well have a persistence of ancestral characters—in the wild asses and zebras the mane is always short, and they never have long persistent hairs at the proximal end of the tail.

Though a superficial examination may lead one to think with Flower that Przewalsky's horse is an accidental hybrid, a careful study of the soft parts and skeleton inevitably leads to quite a different conclusion. Though failing to understand why so many zoologists persisted in considering the horse of the Great Gobi Desert to be a mule, I decided to breed a number of Kiang-horse hybrids.[2]

Adderley.

FIG. 1.—Kiang pony Hybrid, *æt.* two days.

With the help of Lord Arthur Cecil, I succeeded early in 1902 in securing a male wild Asiatic ass and a couple of Mongolian pony mares—one a yellow-dun, the other a chestnut. "Jacob," the wild ass, was mated with the dun Mongol mare, with a brownish-yellow Exmoor pony, and with a bay Shetland-Welsh pony. The chestnut Mongol pony was put to a light grey Connemara stallion. Of the four mares referred to, three have already (June) foaled, viz. the Exmoor and the two Mongolian ponies. The Exmoor having foaled first, her hybrid may be first considered.

1 The Wild Horse (*Equus przewalskii*, Poliakoff). By Prof. J. C. Ewart, F.R.S. Read before the Royal Society of Edinburgh, June 15.

1 Beddard, "Mammalia," p. 240. (Macmillan, 1902.)

2 Sir William Flower, the late president of the London Zoological Society, having more than hinted in 1891 that Przewalsky's horse was a mule, one would have thought an effort would have been made forthwith to test this view in the Society's Garden.

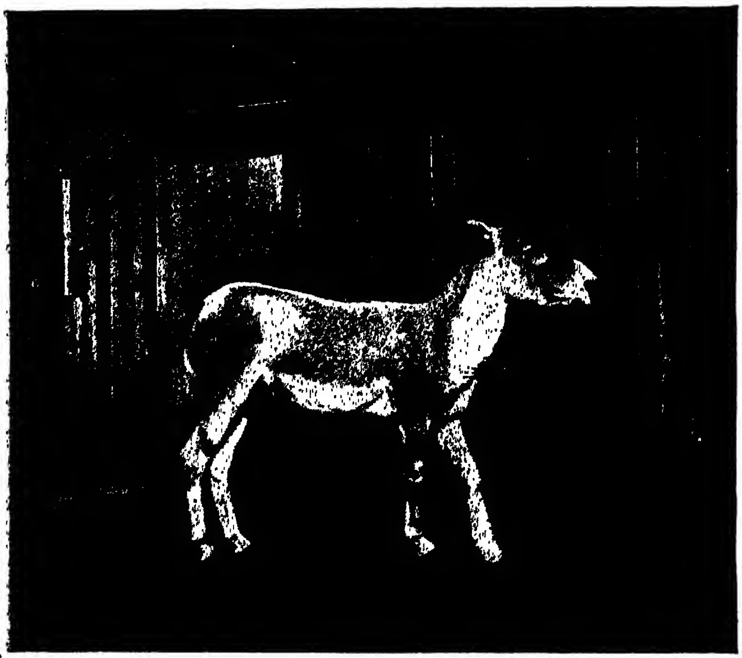
It may be mentioned that the Exmoor pony had, in 1900, and again in 1901, a zebra hybrid, the sire being the Burchell zebra "Matopo," used in my telegony experiments. In the case of her Kiang hybrid the period of gestation was 335 days (one day short of what is regarded as the normal time), but she carried her 1900 zebra hybrid 357 days, three weeks beyond the normal time. The Exmoor-zebra hybrids are as nearly as possible intermediate between a zebra and a pony; the Kiang-hybrid, on the other hand, might almost pass for a pure-bred wild ass.[1] In zebra hybrids the ground colour has invariably been darker than in the zebra parent; but the Kiang hybrid is decidedly lighter in colour than her wild sire, while in make she strongly suggests an Onager—the wild ass so often associated with the Runn of Cutch. Alike in make and colour, the Kiang hybrid differs from a young Przewalsky foal.[2]

I have never seen a new-born wild horse, but if one may judge from the conformation of the hocks, from the coarse legs, big joints, and large heads of the yearlings—from their close resemblance to dwarf cart-horse foals—it may be assumed they are neither characterised by unusual agility nor fleetness. The Kiang hybrid, on the other hand, looks as if built for speed, and almost from the moment of its birth it has, by its energy and vivacity, been a source of considerable anxiety to its by no means placid Exmoor dam. When four days old it walked more than twenty miles; on the fifth day, instead of resting, it was unusually active, as if anxious to make up for the forced idleness of the previous evening. In the hybrid the joints are small, and the legs are long and slender and covered with short close-lying hair. In the wild horse the joints are large, and the "bone" is round as in heavy horses.

As to its colour, it may be especially mentioned that the hybrid has more white around the eyes than the wild horse, but is of a darker tint along the back and sides and over the hind quarters. Too much importance, however, should not be attached to differences in colour, for, though the two hybrid foals which have already arrived closely agree in their coloration, subsequent foals may differ considerably, and it is well known that young wild horses from the western portions of the Great Altai Mountains differ in tint from those found further east.

Of more importance than the coat-colour is the nature of the hair. A Przewalsky foal has a woolly coat not unlike that of an Iceland foal. In the hybrid, the hair is short and fine, and only slightly wavy over the hind quarters. It thus differs but little from a thoroughbred or Arab foal.

The mane and tail of the hybrid are exactly what one would expect in a mule; the dorsal band, 75mm. wide over the croup in the sire, has in the hybrid a nearly uniform width of 12mm. from its origin at the withers until it loses itself half-way down the tail. The tail, which differs but little from that of a pony foal, is of a lighter brown colour than the short upright mane, while the dorsal band is of a reddish-brown hue. In the wild horse the dorsal band is sometimes very narrow (under 5mm.) and indistinct. In the Kiang sire there are pale but quite distinct stripes above and below the hocks, and small faint spots over the hind quarters—vestiges, apparently, of ancestral markings; but in the hybrid there are neither indications of stripes across the hocks or withers, nor spots on the quarters.[1]



E. Darwin-Wilmot.

Fig. 2.—Sire of Hybrid.

In having no indications of bars on the legs or faint stripes across the shoulders, the hybrid differs from Przewalsky colts; it also differs in having a longer flank feather, and in the facial whorl being well below the level of the eyes. As in the Kiang and wild horse, the under surface of the body and the inner aspect of the limbs are nearly white.

In the hybrid the front chestnuts (wrist callosities) are smooth and just above the level of the skin, but instead of being roughly pear-shaped as in the Kiang, they are somewhat shield-shaped, as in the Onager. In the wild horse the front chestnuts are elongated.

In the Exmoor dam the hind chestnuts (hock callosities) are 27mm. in length and 10mm. wide. In the sire there is a minute callosity inside the right hock. In the hybrid the hind chestnuts are completely absent. In the absence of hock callosities the hybrid differs from the wild horse, in which they are relatively longer than in Clydesdales, Shires, and other heavy breeds of horses. In the hybrid, as in the sire and dam, there are smooth, rounded fetlock callosities (ergots) on both fore and hind limbs.

In the wild horse the hoof is highly specialised, the "heels" being bent inwards (contracted) to take a vice-like grip of the frog. In the hybrid the hoof closely resembles that of the pony dam; it is shorter than in the Kiang, and less contracted at the "heels" than in the wild horse.

The Kiang hybrid further differs from a young wild

[1] The wild parent is generally prepotent over the tame—in Mendelian terms the Kiang proved dominant, the Exmoor pony recessive.

[2] For a skin of a very young Przewalsky foal I am indebted to Mr. Carl Hagenbeck, of Hamburg.

[1] The complete absence of stripes in the Kiang hybrid is all the more interesting, seeing that the dam's previous foals were zebra hybrids. Evidently the Kiang hybrid lends no support to the telegony doctrine.

horse in the lips and muzzle, the nostrils and ears, and in the form of the head.

The wild horse has a coarse, heavy head, with the lower lip (as is often the case in large-headed horses and in Arabs with large hock callosities) projecting beyond the upper. The nostrils in their outline resemble those of the domestic horse, while the long pointed ears generally project obliquely outwards, as in many heavy horses and in the Melbourne strain of thoroughbreds. Further, in the wild horse the forehead is convex from above downwards, as well as from side to side—hence Przewalsky's horse is sometimes said to be ram-headed. In the hybrid the muzzle is fine as in Arabs, the lower lip is decidedly shorter than the prominent upper lip, the nostrils are narrow as in the Kiang, and even at birth the forehead was less rounded than is commonly the case in ordinary foals. The ears of the hybrid, though relatively shorter and narrower than in the Kiang, have, as in the Kiang, incurved dark-tinted tips, and they are usually carried erect or slightly inclined towards the middle line. In the wild horse the croup is nearly straight, and the tail is set on high up, as in many desert Arabs. In the hybrid the croup slopes as in the Kiang and in many ponies, with the result that the root of the tail is on a decidedly lower level than the highest part of the hind quarters. Further, in the young wild horses I have seen the heels (points of the hocks) almost touch each other, as in many Clydesdales, and the hocks are distinctly bent. In the hybrid the hocks are as straight as in well-bred foals, and the heels are kept well apart in walking.

Another difference of considerable importance is that while the wild horse neighs, the hybrid makes a peculiar barking sound, remotely suggestive of the rasping call of the Kiang.

The dun Mongol pony's hybrid arrived five weeks before its time, and, though perfect in every way, was short-lived. Only in one respect did this hybrid differ from the one already described. In the Exmoor hybrid the hock callosities are entirely absent; in the Mongol hybrid the right hock callosity is completely wanting, but the left one is represented by a small, slightly hardened patch of skin sparsely covered with short white hair.[1] In zebra hybrids out of cross-bred mares the hock callosities are usually fairly large, while in hybrids out of well-bred ("Celtic") pony mares the hock callosities are invariably absent. The Exmoor pony, though not so pure as the Hebridean and other ponies without callosities, has undoubtedly a strong dash of true pony blood; the Mongol pony is as certainly saturated with what, for want of a better term, may be called cart-horse blood. As I expected, there were no hock callosities present in the Exmoor hybrid. In the Mongol hybrid there was less evidence of hock callosities than I expected.

From what has been said it follows that a Kiang-horse hybrid differs from Przewalsky's horse (1) in having at the most the merest vestiges of hock callosities; (2) in not neighing like a horse; (3) in having finer limbs and joints and less specialised hoofs; (4) in the form of the head, in the lips, muzzle, and ears; (5) in the dorsal band; and (6) in the absence, even at birth, of any suggestion of shoulder-stripes and of bars on the legs.

While most of the zoologists who hesitated to regard Przewalsky's horse as representing a distinct and primitive type favoured the view that it was a mule, some asserted that it in no way essentially differed from an ordinary horse. The colts brought from Central Asia, they said, were the offspring of escaped Mongol ponies. Others affirmed that they failed to discover any difference between the young wild horses in the London Zoological Gardens and Iceland ponies of a like age. To test the first of these assertions, I, as already mentioned, mated the chestnut Mongol pony with a young Connemara stallion; to test the second, I purchased last autumn a recently-imported yellow-dun Iceland mare in foal to an Iceland stallion. As I anticipated, the chestnut Mongol mare produced

a foal the image of herself. This foal, it is hardly necessary to say, decidedly differs from the Przewalsky colts recently imported from Central Asia by Mr. Hagenbeck, and it as decidedly differs from the Kiang hybrids described above.

The Iceland foal, notwithstanding the upright mane and the woolly coat, for a time of a nearly uniform white colour, could never be mistaken for a wild horse, and the older it gets the differences will become accentuated.

If Przewalsky's horse is neither a Kiang-pony mule nor a feral Mongolian pony, and if, moreover, it is fertile (and its fertility can hardly be questioned), I fail to see how we can escape from the conclusion that it is as deserving as, say, the Kiang to be regarded as a distinct species. Granting Przewalsky's horse is a true wild horse, the question arises: In what way, if any, is it related to our domestic horses? It is still too soon to answer this question; but I venture to think that should we, by and by, arrive at the con-

[1] The presence of hair in the imperfectly-formed hock callosity of the Mongol hybrid, together with the presence of hair rudiments in the developing hock callosity of the common horse, certainly lends very little support to the view held by some zoologists that the chestnuts of the horse are vestiges of glands.

clusion that our domestic horses have had a multiple origin—have sprung from at least two perfectly distinct sources—we shall probably subsequently come to the further conclusion that our big-headed, big-jointed horses, with well-marked chestnuts on the hind legs, are more intimately related to the wild horse than the small-headed, slender-limbed varieties without chestnuts on the hind legs; that, in fact, the heavy horses, whether found in Europe, Asia, or Africa, and Przewalsky's horse have sprung from the same ancestors.

HIGHER TECHNICAL EDUCATION IN GREAT BRITAIN AND GERMANY.[1]

H.M. Consul at Stuttgart, Dr. Frederick Rose, has rendered excellent service to the cause of technical education by the admirable reports which he has from time to time sent to the Foreign Office; but no previous report of his presents such a clear view of the extent of the provisions for technical education in Germany and of the nature of the services which the technical high schools render to the nation as does the one recently published by the Foreign Office.
